USPTO CUSTOMER NO. 41552

METHOD FOR TREATING ALZHEIMER'S DEMENTIA

This application claims benefit of the filing date of U.S. Provisional Application No. 60/456,869, filed March 21, 2003, and which is incorporated by reference.

This invention was made with government support under grant numbers 1R43 AG18044-01 and 1R43 AG18044-02 awarded by the National Institutes of Health. The government may have certain rights in aspects of the invention.

BACKGROUND OF THE INVENTION

The present invention relates generally to methods for treatment and prevention of dementia and, more specifically, to novel strategies for treatment and prevention of Alzheimer's disease.

Dementia is a neurological disease that results in loss of mental capacity and is associated with widespread reduction in the number of nerve cells and brain tissue shrinkage. Memory is the mental capacity most often affected by dementia. The memory loss may first manifest itself in simple absentmindedness, a tendency to forget or misplace things, or to repeat oneself in conversation. As the dementia progresses, the loss of memory broadens in scope until the patient can no longer remember basic social and survival skills and function independently. Dementia can also result in a decline in the patient's language skills, spatial or temporal orientation, judgment, or other cognitive capacities. Dementia tends to run an insidious and progressive course.

Alzheimer's Disease (AD) is a degenerative brain disorder presented clinically by progressive loss of memory, cognition, reasoning, judgement, and emotional stability that gradually leads to profound mental deterioration and ultimately death. Individuals with AD exhibit characteristic beta amyloid deposits in the brain (beta amyloid plaques) and in cerebral blood vessels (beta amyloid angiopathy) as well as neurofibrillary tangles. On autopsy of AD patients, large numbers of these lesions, which are believed to be a causative precursor or factor in the development of disease, are generally found in areas of the human brain important for memory and congnitive function. Smaller numbers are found in the brains of most aged humans not showing clinical symptoms of AD. Beta amyloid plaques and beta amyloid angiopathy also characterize the brains of individuals with Down's Syndrome (Trisomy 21) and Hereditary Cerebral Hemorrhage with Beta amyloidosis of the Dutch-Type, and other such disorders.

Beta amyloid plaques are predominantly composed of beta amyloid beta peptide, which is interchangeably referred to herein as AB peptide and Aβ peptide and, sometimes designated betaA4 in the art. The major components of amyloid plaques are the amyloid ß-peptides, also called Aß, AB or Abeta peptides, which consist of three proteins having 40, 42 or 43 amino acids, designated as the $A\beta_{1-40}$, $A\beta_{1-42}$, and $A\beta_{1-43}$ peptides. The amino acid sequences of the Aß peptides are known and the sequence of the $A\beta_{1-42}$ is identical to that of the $A\beta_{1-40}$ peptide, except that the $A\beta_{1-42}$ peptide contains two additional amino acids at its carboxyl (COOH) terminus. Similarly, the amino acid sequence of the $A\beta_{1-43}$ peptide is identical to that of the $A\beta_{1-42}$ peptide except that the $A\beta_{1-43}$

peptide contains one additional amino acid at its carboxyl terminus. The Aß peptides are thought to cause the nerve cell destruction in AD, in part, because they are toxic to neurons *in vitro* and *in vivo*.

The Aß peptides are derived from larger amyloid precursor proteins (APP proteins), which consist of four proteins, designated as the APP_{695}, APP_{714}, APP_{751}, and APP_{771} proteins, which contain 695, 714, 751 or 771 amino acids, respectively. The different APP proteins result from alternative ribonucleic acid splicing of a single APP gene product. The amino acid sequences of the APP proteins are also known and each APP protein contains the amino acid sequences of the Aß peptides.

Proteases are believed to produce the Aß peptides by recognizing and cleaving specific amino acid sequences within the APP proteins at or near the ends of the Aß peptides. Such sequence specific proteases are thought to exist because they are necessary to produce from the APP proteins the $A\beta_{1-40}$, $A\beta_{1-42}$, and $A\beta_{1-43}$ peptides consistently found in plaques. These proteases have been named "secretases" because the Aß peptides which they produce are secreted by cells into the extracellular environment. Moreover, the secretases have been named according to the cleavages that must occur to produce the Aβ peptides. The secretase that cleaves the amino terminal end of the Aß peptides is called the ß-secretase and that which cleaves the carboxyl terminal end of the Aβ peptides is called the γ-secretase. The γ-secretase determines whether the $A\beta_{1-40}$, $A\beta_{1-42}$, or $A\beta_{1-43}$ peptide is produced.

In addition to the proteolytic cleavage that produces the Aß peptides, proteolytic cleavage of another specific amino acid sequence within the APP proteins is known to occur and to produce α-APP and 10 kilodalton (kDa) fragments. That amino acid sequence lies within the Aß peptide amino acid sequence of the APP proteins. Significantly, the products produced by the α-secretase cleavage, the α-APP and the 10 kilodalton (kDa) fragments, do not form senile plaques.

At present there are no effective treatments for halting, preventing, or reversing the progression of Alzheimer's disease and treatment is primarily supportive. Stimulated memory exercises on a regular basis have been shown to slow, but not stop, memory loss. A few drugs, such as tacrine, result in a modest temporary improvement of cognition but do not stop the progression of dementia.

Thus, an urgent need exists for pharmaceutical agents capable of preventing or slowing the progression of Alzheimer's disease, such as agents that are effective inhibitors of β-secretases; agents that inhibit β-secretase-mediated cleavage of APP; agents that are effective inhibitors of Aβ peptide production; and agents effective to reduce beta amyloid beta deposits or plaques. The present invention satisfies this need and provides additional advantages as well.

SUMMARY OF THE INVENTION

The invention is directed to a method of selecting an agent that prevents cleavage of an APP substrate by contacting a candidate agent with a β-secretase complex that encompasses cathepsin B and cathepsin L, wherein the contacting occurs in the presence of an APP substrate and under conditions that allow for cleavage of the APP substrate by the β-secretase complex; and selecting the agent that prevents the cleavage of the APP substrate by the β-secretase complex.

The invention also provides a method of decreasing the production of an Aβ peptide by a cell by contacting the cell with the agent selected by the invention method and thereby decreasing production of the Aβ peptide by the cell.

The invention further is directed to a method of selecting an agent that prevents cleavage of an APP substrate by contacting a candidate agent with an individual component of the β-secretase complex, either cathepsin B and cathepsin L, in the presence of an APP substrate and under conditions that allow for cleavage of the APP substrate by said β-secretase; and selecting the agent that prevents the cleavage of the APP substrate by the β-secretase.

The present invention also provides a method of decreasing the production of an Aβ peptide by a cell comprising contacting the cell with the agent that prevents cleavage of an APP substrate selected by the disclosed

method. The selected agent can be specific with regard to inhibition of either cathepsin B or cathepsin L, but also can have inhibitory activity vis-a-vis both of these β-secretases.

Also provided by the present invention is a method of decreasing production of an Aβ peptide by an individual affected with a condition associated with aggregation of the Aβ peptide into amyloid plaques by administering to the affected individual an effective amount of the agent selected by the by the invention method and thereby decreasing production of the Aβ peptide by the affected individual.

In one embodiment of the invention, decreasing production of the Aβ peptide by the individual results in a reduction of the Aβ peptide into amyloid plaques. Thus, the invention provides a method of reducing the severity of a condition characterized by amyloid plaque formation such as Alzheimer's Disease.

The invention further provides a method of reducing the severity of a condition associated with an activity of cathepsin B by administering an effective amount of an agent selected by the disclosed methods to an individual affected with a condition associated with an activity of cathepsin B.

In a distinct embodiment, the invention provides a method of reducing the severity of a condition associated with an activity of cathepsin L by administering an effective amount of an agent selected by the disclosed

methods to an individual affected with a condition associated with an activity of cathepsin L.

Also provided is a method of reducing the severity of a condition associated with an activity of cathepsins B and L by administering an effective amount of an agent selected by the disclosed methods to an individual affected with a condition associated with an activity of each, cathepsins B and L.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1. The upper bar is a diagram of an amyloid precursor protein (APP protein). The amino and carboxyl termini of the APP protein are indicated by the letters "N" and "C," respectively. The relative location of various known regions within the APP protein are indicated, including the signal peptide (SP), cysteine-rich (C-rich), negatively charged ((-)charged), protease inhibitor, Ox antigen (Ox), transmembrane, cytoplasmic and Aβ peptide regions. The amino acid sequence of the Aβ peptides and regions flanking the Aβ peptides is shown by the letters below the amyloid precursor protein (SEQ ID NO.:1). Each letter represents an amino acid according to the conventional single letter amino acid abbreviation format. Scissile bonds within the amino acid sequence cleaved by the β-, γ-, or α- secretases are indicated by the β, γ, and α labels. Three scissile bonds cleaved by β-secretases which, in combination with scissile bond cleaved by the γ-secretase, produce the $A\beta_{1-40}$, $A\beta_{1-42}$, or $A\beta_{1-43}$ peptide. The three parallel lines below the amino acid sequence identify

the amino acid sequences of the $A\beta_{1-40}$, $A\beta_{1-42}$, and $A\beta_{1-43}$ peptides.

Figure 2. The bonds, labeled #1, #2, and #3, in the Z*Val-Lys-Met-MCA substrate cleaved by a secretase having endoprotease activity are shown. The Z, Val, Lys, Met, and MCA in the substrate represent a carbobenzoxy, valine, lysine, methionine, and aminomethylcourmarinamide group, respectively. The star (*) and dash (-) represent nonpeptide and peptide bonds, respectively

Figure 3. The fluorescence activity is plotted as a function of the pH at which a lysate of substantially pure chromaffin vesicles is incubated with the Z*Val-Lys-Met-MCA substrate. The fluorescence activity is the relative fluorescence of the free MCA (AMC) released by proteolytic cleavage of the substrate.

Figure 4. The fluorescence activity is plotted as a function of the pH at which a lysate of substantially pure chromaffin vesicles is incubated with the Met-MCA substrate. The fluorescence activity is the relative fluorescence of the free MCA (AMC) released by proteolytic cleavage of the substrate.

Figure 5. The fluorescence activity is plotted as a function of the pH at which the lysate of substantially pure chromaffin vesicles is incubated with the Lys-MCA substrate. The fluorescence activity is the relative fluorescence of the free MCA (AMC) released by proteolytic cleavage of the substrate.

Figure 6. The fluorescence activity is plotted as a function of the pH at which the lysate of substantially pure chromaffin vesicles is incubated with the Z*Val-Lys-Met-MCA substrate in the presence and absence of DTT (closed and open squares, respectively). The fluorescence activity is the relative fluorescence of the free MCA (AMC) released by proteolytic cleavage of the substrate.

Figure 7. The fluorescence activity is plotted as a function of the pH at which the lysate of substantially pure chromaffin vesicles is incubated with the Z*Val-Lys-Met-MCA substrate in the presence of DTT without aminopeptidase M (open triangles), with basic pH buffer (open squares), or with aminopeptidase M (closed squares). The fluorescence activity is the relative fluorescence of the free MCA (AMC) released by proteolytic cleavage of the substrate.

Figures 8. The isolation procedure used to obtain Peak I and Peak II is diagramed.

Figure 9. The fluorescence activity is plotted as a function of the fraction number (#) obtained from the Sephacryl S200 in the procedure diagramed in Figure 8. Fraction numbers 30 to 40, and 40 to 50 contain Peak I and Peak II, respectively. The activity is that which results from cleavage of the Z*Val-Lys-Met-MCA substrate by the fraction without aminopeptidase M (open squares), or with aminopeptidase M (closed squares). The fluorescence activity is in pmol of free MCA per microliter (AMC/µl).

The γ-globulin, BSA, and myoglobin are calibration weight standards.

Figure 10. The procedure used to isolate the β-secretases from Peak I is diagramed.

Figure 11. The procedure sued to isolate the β-secretases from Peak II is diagramed.

DETAILED DESCRIPTION OF THE INVENTION

The present invention is based on the discovery that the cysteine proteases cathepsin L and cathepsin B are the ß-secretases contained in distinct purifications of ß-secretases that were previously designated as Peak I and Peak II, respectively, as described by Hook et al., J. Neurochem. 81:237-256 (2002), which is incorporated herein by reference in its entirety. The discovery that cathepsin L and cathepsin B are the β-secretases responsible for producing the amino terminal end of amyloid peptides (Aβ) peptides by enzymatic cleavage of the precursor protein APP holds tremdenous promise for treatment of conditions associated with overproduction of Aβ peptides.

The present invention thus provides a significant advantage for the development of new treatments of conditions associated with overproduction of Aβ peptides by allowing for exploitation of the discovery that APP is a substrate for cathepsins L and B. The presence in the central nervous system of beta amyloid plaques composed of and resulting from the overproduction of Aβ peptides is a defining feature of Alzheimer's Disease and believed to be a

causative precursor or factor in the development and progression of the disease.

In one embodiment, the invention is directed to a method of selecting an agent that prevents cleavage of an APP substrate by contacting a candidate agent with a β-secretase complex that encompasses cathepsin B and cathepsin L, wherein the contacting occurs in the presence of an APP substrate and under conditions that allow for cleavage of the APP substrate by the β-secretase complex; and selecting the agent that prevents the cleavage of the APP substrate by the β-secretase complex.

In a further embodiment, the invention is directed to a method of selecting an agent that prevents cleavage of an APP substrate by contacting a candidate agent with a β-secretase species, either cathepsin B or cathepsin L, in the presence of an APP substrate and under conditions that allow for cleavage of the APP substrate by the β-secretase species; and selecting the agent that prevents the cleavage of the APP substrate by the β-secretase species.

The invention also provides a method of decreasing the production of an Aβ peptide by a cell by contacting the cell with the agent selected by the invention method and thereby decreasing production of the Aβ peptide by the cell.

Cathepsins are a family of enzymes which are part of the papain superfamily of cysteine proteases. Cathepsins B, H, K, L, N and S have been described in the literature. Cathepsins function in the normal physiological process of

protein degradation in animals, including humans, for example, in the degradation of connective tissue. However, elevated levels of these enzymes in the body can result in pathological conditions leading to disease. Thus, cathepsins have been implicated as causative agents in various disease states, including but not limited to, infections by *Pneumocystis carinii, Trypsanoma cruzi, Trypsanoma brucei brucei*, and *Crithidia fusiculata*, as well as in schistosomiasis, malaria, tumor metastasis, metachromatic leukodystrophy, muscular dystrophy, amytrophy, and the like. See International Publication Number WO 94/104172, published on Mar. 3, 1994, and references cited therein. See also European Patent Application EP 0 603 873 A1, and references cited therein. Two bacterial cysteine proteases from *P. gingivallis*, called gingipains, have been implicated in the pathogenesis of gingivitis. Potempa, J., et al., Perspectives in Drug Discovers and Design, 2, 445-458 (1994).

Cathepsin L plays an important role in various syndromes. Cathepsin L is of importance for the invasiveness of tumors and the formation of metastases. This protease can also be involved in the penetration of pathogenic bacteria or parasitic protozoa into the host tissue. Cathepsin L is also involved in the degradation of bone matrix. This enzyme also appears to be a target in connection with the treatment of osteoporosis (Pharma Japan, September 1995, 1468, 23). Cathepsin L is also involved in the development of inflammatory diseases such as arthritis.

Recently, the cyseine proteases of Peak I and Peak II were shown to contain the vast majority of in vivo ß-secretase activity, accounting for approximately 95% of the Aß peptide production (Hook et al., J. Neurochem. 81:237-256, 2002). In particular, the cysteine proteases in those Peaks were shown to be particularly effective at cleaving the ß-secretase site in wild-type APP, the APP present in over 95% of AD patients. As such, inhibition of that ß-secretase activity is an effective means by which to reduce treat AD.

The instant discovery that cathepsin L and cathepsin B are the ß-secretases contained in distinct purifications of ß-secretase, designated Peak I and Peak II, respectively, now allows for the use of those cathepsins as screens for selecting AD drugs. In particular, such screens can be used to select for compounds that are themselves effective for treating AD or for compounds that will lead to development of such compounds.

As used herein, the term "activity" when used in reference to cathepsin L or cathepsin B or both refers a ß-secretase activity or any enzymatic cleavage of a substrate that results in production of an Aβ peptide. Many methods are known in the art for using a known protease as a target to select compounds that inhibit it and any of those methods can be adopted to screen for compounds that effect an activity of cathepsin L and cathepsin B. Such means include, for example, those based on *in vitro* chemical reactions between a compound and a cathepsin L or cathepsin B molecule. In such a system, a compound's effect on the enzymatic activity of cathepsin L or cathepsin B on an APP

substrate can be assayed and inhibitors selected that reduce the activity. The reduced ß-secretase activity can be assayed by any means known or those described herein For example, the reduced ß-secretase activity caused by such a compound can be assayed by detecting a reduced production of one or more AB peptides or a reduced production of the 12 -14 kDa COOH-terminal APP fragment that contains the ß-secretase domain. Such production can be detected by any means known in the art for doing so and those described herein. Such inhibitors can act by any means that effects the activity of cathepsin L or cathepsin B or both. For example, an inhibitor can bind to the active site on a cathepsin L or cathepsin B molecule and thereby reduce the activity of the cathepsin. An inhibitor can also act by binding to a domain distal to the active site on a cathepsin L or cathepsin B molecule and thereby reduce the activity. The compound can also inhibit by binding to the APP substrate and thereby block its cleavage by the cathepsin.

In vitro chemical reactions also include those between a compound and one or more other molecules known to effect the production of cathepsin L or B. For example, cells are known to produce enzymatically inactive procathepsin L and procathepsin B froms which are proteolytically cleaved into enzymatically active forms. The amino acid and nucleic acid sequences of procathepsin L and procathepsin B are known as are many enzymes capable of producing active cathepsin L and cathepsin B. Thus, compounds can be selected for that inhibit the proteolytic conversion of procathepsin L and procathepsin B to cathepsin L and cathepsin B, respectively, and thereby reduce cathepsin L and cathepsin B activity.

In vitro chemical reactions also include those between a compound and one or more other molecules known to effect the activity of cathepsin L or B. Many molecules are known in the art to effect cathepsin L or cathepsin B activity. For example, the molecule P41, a splice variant of the major histocampatibility complex (MHC) class II associated invariant chain contains a segment that acts as a chaparone for cathepsin L by both inhibiting the activity of cathepsin L and stabilizing its structure. Thus, in vitro chemical reactions can select for compounds that alter the effect of P41 on the cathepsin L activity. Other molecules are also known in the art to effect the activity of cathepsin L and cathepsin B and any of these molecules can also be used to select for AD compounds.

Assays also include cell assays that select for compounds that inhibit ß-secretase activity of cathepsin L or cathepsin B. For example, as described herein, chromaffin or neuronal cells can be used for this purpose. The reduction in activity in such cells can be determined by a variety of means such as, for example, by detecting the reduction in the production of one or more AB peptides or a reduced production of the 12 -14 kDa COOH-terminal APP fragment that contains the ß-secretase domain. In particular, AB peptide production can be detected in cells induced to undergo exocytosis as described herein. A compound can reduce the activity of cathepsin L or cathepsin B activity in such cell assays by a variety of means. For example, a compound can reduce the ß-secretase activity by effecting the proteolytic cleavage capability of cathepsin L or cathepsin B for APP substrates. A compound can also inhibit that activity by reducing the production of

cathepsin L or cathepsin B. The production can be effected at any point in the cell production of cathepsin L or cathepsin B, including at the transcription, translation, and post-translational processing levels.

Assays also include animal assays for selecting compounds that reduce the ß-secretase activity of cathepsin L or cathepsin B. The reduction in that activity can be assayed by a variety of means such as, for example, by detecting a reduction in the production of one or more AB peptides by means known in the art or described herein. In a particular embodiment, the production of AB peptide in the central nervous system can be assayed. Normal or known transgenic AD model animals can be used for this purpose. Assays also include patient assays for monitoring the effectiveness of such inhibitors for reducing AB peptide production in patients. In particular, such methods as those described in U. S. Patent No. 5,338,686, can be adapted to measure production of one or more AB peptides by a patient receiving such an inhibitor.

Assays further include in silico assays that select for compounds based on the known structure of cathepsin L or cathepsin B. Such structural analysis can be based on a wide range of data sources ranging, for example, from the known amino acid sequence structure to the known three-dimensional atomic resolution crystal structure of cathepsin L or cathepsin B. Especially useful crystal structures for this purpose are the active sites of the cathepsins in which APP substrates are cleaved (see, for example, Fujishima, A. et al., Febs. Lett. 407:47-50, 1997; Guncar G, et al. EMBO J. 1999 Feb 15;18(4):793-803; Yamamoto A, et al., J Biochem (Tokyo), 2000 Apr;127(4):635-43;

Yamamoto A, et al. J Biochem (Tokyo). 2000 Apr; 127(4):635-43; Yamamoto A, et al., Biochim Biophys Acta. 2002 Jun 3;1597(2):244-51). Moreover, the assays also include those based on rational drug design using known structures of compounds that effect cathepsin L or cathepsin B activity or structure. Such in silico assays are known in the art and can be readily applied to determine effective inhibitors.

In addition to sreening for agents that inhibit ß-secretase activity of cathepsin L or cathepsin B, the methods of the invention also can be performed with known inhibitors of these β secretases. The ability of such known inhibitors with regard to inhibiting an activity of cathepsin L or cathepsin B or both with regard to the cleavage of an APP substrate can subsequently be confirmed via routine assays described herein.

Numerous inhibitors of cathepsin L or cathepsin B are known in the art. Such agents found by searching the literature using known methods for doing so including, for example, by finding such compounds via computer searches of data bases, such as patent and scientific publication data basis. Inhibitors known to be effective *in vivo* for altering cathepsin L or cathepsin B activity can be as AD drugs or further developed into even more effective drugs using known medicinal chemistry methods. Inhibitors not known to be effective *in vivo* can, nonetheless, be used to develop AD drugs using known medicinal chemical methods.

Compounds known that inhibit cysteine proteases generally can be used for such purposes. Such compounds are described, for example, in U.S. Patent Nos. 5,925,633, 5,925,772, 5,776,718, 6,458,760 and 6,468,977. Such compounds include, for example, E64c and derivatives thereof, such as, for example, E64d. E64c has been administered to animals and shown to effectively block cathepsin activity in brain.

Many compounds are known to selectively inhibit cathepsin L that can be used as AD drugs or AD drug development. For example, a series of inhibitors referred to as cathepsin L inhibitor Katunuma (CLIK) have been developed which were found to selectively inhibit cathepsin L (see, for example, Katunuma et al., FEBS Lett. 458:6-10, 1999, Katunuma et al., Arch. Biochem & Biophy. 397:305-311, 2002a, and Katunuma et al., Advan. Enzyme Regul. 42:159-172, 2002b). These compounds are based on a common structure of N-(trans-carbamoyloxyrane-2-carbonyl)-L-phenylalanine-dimethylamide. The prototype compound of this series of inhibitors is CLIK-148 (N-(L-3-trans-[2-(pyridin-2-yl)ethylcalbamoyl-oxirane-2-calbonyl]-1-phenylalanine dimethylamide. CLIK-148 inhibited purified rat cathepsin L activity in the submicromolar levels and completely inhibited activity at 1 uM (Katunuma et al. 1999). In contrast, it had no effect on purified rat cathepsin B activity at 10 uM and only had minimal activities on cathepsins K, S and C at micromolar levels. Intraperitoneal injection of CLIK-148 to mice dose dependently inhibited cathepsin L activity in liver while having no effect on cathepsin B activity (Katunuma et al. , 1999, ibid). Both cancer metastasis and osteoporosis are

believed to be due to actions of cathepsin L in degrading collagen. Intravenous or p.o. administration of CLIK-148 blocked bone metastasis of the cancer cells Colon-26 and the human melanoma cells A375 in mice and blocked cancer induced osteoporosis (Katunuma et al. 2002a, ibid) consistent with the inhibitory actions of CLIK-148 on cathepsin L activity.

Additional cathespin L inhibitors were developed by Rydzewski et al. Bioorganic & Medicinal Chem. 10:3277-3284, 2002 using a 1-cyano-D-proline scaffold. In particular, the compound 1-cyano-(D)-prolylleucine benzyl ester was developed that selectively inhibits cathepsin L and that compound completely inhibited cathepsin L activity in DLD-1 cells while having minimal activity on cathespin B.

Many other compounds have been found to inhibit cathepsin L. Such compounds include those described by Chowdhurry, SF., et al., J, Med. Chem. 45(24):5321-5329, 2002; Yamamoto, Y. et al,, Curr . Protein Pept. Sci. 3(2):231-238, 2002; Asanuma, K., et al., Kidney Int. 62(3):822-831, 2002; Saegusa, K., et al., J. Clin. Invest. 110(3):361-369, 2002; Rigden., DJ., Protein Sci. 11(8):1971-1977, 2002; Schaschke., N. et al., Biol. Chem. 383:849-852, 2002; Sever, N.et al., Bio. Chem. 383(5):839-842, 2002; Wang., D., et al., Biochemistry 41(28):8849-8859, 2002; Katunuma, N., et al. Arch. Biochem. Biophys. 397(2):305-311, 2002; Irving, JA, et al. J. Biol. Chem. 277(15):13192-13201, 2002; Kurata, M., et al., J. Biochem (Tokyo) 130(6):857-863, 2001; Kusunoki, T., et al. J. Otolaryngol. 30(3):157:161, 2001; United States Patent No. 5,698,519; United States Patent No. 5,883,121; United

States Patent No. 5,955,491; United States Patent No. 6,353,017).

Many compounds are also known to selectively inhibit cathepsin B and can be used for AD drugs or drug development. For example, compounds have been developed that are selective cathespin B inhibitors based on a series of dipeptidyl nitriles starting with the compound' Cbz-Phe-NH-CH2CN (see, for example, Greenspan et al., J. Med. Chem 44:4524-4534, 2002). In particular, the compound N-[2-[(3-Carboxyphenyl)methoxyl-1-(S)-cyanoethyl]-3-methyl-N-(2,4-difluorobenzoyl)-L-phenylalaninamide has been shown to inhibit recombinant human cathepsin B activity but is approximately 100-fold less potent in blocking cathepsin L or cathepsin S activities.

The compound CA-074 has also been shown to be a selective inhibitor of cathepsin B (see, for example Jane, DT., et al., Biochem Cell Biol. 80(4):457-465, 2002; and Montaser, M., et al., Bio Chem. 383(7-8):1305-1308, 2002).

Many other compounds are also known to selectively inhibit cathpsin B. Such compounds include those described by Niestroj, AJ., et al. Biol. Chem. 383(7-8):1205-1214, 2002; Cathers, BE., et al. Bioorg. Chem. 30(4):264, 2002; Guo,. R., et al. Biochem Biophys. Res. Commun. 297(1):38-45, 2002; Wieczerzak, E, et al. J. Med. Chem. 45(19):4202-4211, 2002; Van Ackjer, GJ., et al., Am. J. Physiol. Gastrointest. Liver Physiol. 283(3): G794-800, 2002; Schaschke, N., et al. 2002, ibid; Sever, N., et al., 2002, ibid; Wang et al., 2002 ibid; Yamamoto, A. 2002 ibid; Irving, JA., 2002 ibid; and United States Patent No. 5,550,138; United States Patent

No. 5,691,368; United States Patent No. 6,143,931; United States Patent No. 6,353,017)

As discussed in Examples V and VII below, the secretory vesicles of chromaffin cells of the adrenal medulla, herein called "chromaffin vesicles," were discovered to contain Aβ peptides, specifically the $A\beta_{1-40}$ and the $A\beta_{1-42}$ peptides, and that chromaffin cells can secrete these peptides. As such, the chromaffin vesicles were found to contain the *in vivo* product produced by APP protein processing. Moreover, the vesicles were known to contain the APP proteins and presenilin 1 protein, a protein that affects secretase activity (see Vassilacopoulou *et al.*, *J. Neurochem.* 64:2140-2146, (1995); Tezapsidis *et al.*, *Biochem.* 37(5):1274-1282, (1998); Borchelt *et al.*, *Neuron* 17:1005-1013, (1996); St. George-Hyslop *et al.*, *Science* 264:1336-1340, (1994); Alzheimer's Disease Collaborative Group, *Nature Genet.* 11:219-222, (1995); and Wasco *et al.*, *Nature Med.* 1:848, (1995)).

Chromaffin vesicles can be obtained in relatively large quantities. That capability, combined with the discovery that the chromaffin vesicles contained the Aβ peptides, permitted for the first time assaying a substantially pure preparation of cell organelles in which APP processing occurs for the proteolytic activity of a secretase. Further, chromaffin vesicles can be obtained in amounts which also permit isolating and sequencing the secretases present in those cell organelles.

As described more fully below in Examples I through XV, bovine chromaffin vesicles were initially discovered to have secretase proteolytic activity. Moreover, it was found that secretases having that activity could be isolated from bovine chromaffin vesicles. But the same methods can be applied to other mammalian species, including humans. As such, secretases from various mammalian species can be assayed for and isolated using the methods disclosed herein.

Further, the amino acid sequence of a bovine secretase is likely to be highly homologous with that of the corresponding human secretase because other bovine proteases are known to have a high degree of homology with the corresponding human protease. For example, the amino acid sequence of the bovine carboxypeptidase H is about 96% homologous with the corresponding human carboxypeptidase H (Hook *et al.*, *Nature*, 295:341-342, (1982); Fricker *et al.*, *Nature*, 323:461-464, (1986); and Manser *et al.*, *Biochem. J.*, 267:517-525, (1990)). Once the amino acid sequence of a secretase from one species is obtained, the corresponding secretase in other species thus can be obtained using recombinant methods such as those described below.

The term "secretase" as used herein means a protease that cleaves an APP protein *in vivo*. A protease is a protein that enzymatically breaks a peptide bond between two amino acids or an amino acid and chemical moiety as described below. Although the term secretase implies the production of a soluble, secreted peptide, an APP derived product produced by a secretase of the invention need not necessarily be soluble or secreted. The term includes those

secretases referred to as β-secretase and γ-secretase, each of which can relate to one or more protease species that produce the Aβ peptides. Secretases also include α-secretases, which can relate to one or more protease species that produce the α-APP fragment or the 10 kDa fragment.

As described in further detail below, the terms "β-secretase" or "β-secretase species" can refer to either or both, cathepsin B and cathepsin L, both of which are individually referred to as β-secretases. In addition, the term "β-secretase complex" refers to a β-secretase that encompasses more than one species, for example, cathepsin B and cathepsin L.

The term "vesicles" as used herein refers to secretory vesicles and condensing vacuoles of the secretory pathway. Such vesicles have a membrane that forms a spherical shaped structure and that separates the contents of the vesicles from the rest of the cell. The vesicles process and store their contents until such time as the contents are secreted into the extracellular environment by a cellular process called exocytosis, which occurs by fusion of the secretory vesicle membrane with the cell membrane. The secretion can occur in response to a triggering event in the cell such as a hormone binding to a receptor. Vesicles can be identified by their characteristic morphology or by the presence of a chemical compound characteristic of such vesicles.

As used herein, the term "substantially pure" as used in regard to vesicles means that at least about 80% of the cell organelles in a sample are vesicles. Usually a substantially pure sample has about 95% or more vesicles and often has about 99% or more vesicles. Substantially pure vesicles include a single isolated vesicle. Substantially pure chromaffin vesicles result after approximately an 8-fold purification from the cell homogenate as described below in Example II.

One aspect of the invention is an assay for determining the proteolytic activity of a secretase by obtaining substantially pure vesicles, permeabilizing the vesicles, and incubating the permeablized vesicles with an APP substrate in conditions which allow the secretase to cleave the APP substrate. The cleavage of the APP substrate is detected and the activity of the secretase is thereby determined.

The vesicles can be obtained from any cell that contains vesicles in which APP protein processing occurs. Vesicles in which such processing occurs can be assayed for by the presence of an Aβ peptide, an α-APP fragment or a 10 kDa fragment in the vesicles using methods described below. Cells containing such vesicles include, for example, neuronal cells from brain tissue, chromaffin cells from adrenal medulla tissue, and platelets from blood. Tissue samples containing such cells can be surgically removed or platelets can be isolated from blood by means known in the art. For tissue samples, the vesicles can be obtained from mechanically homogenized tissue or from tissue disassociated by incubation with collagenase and DNAse (see, for example,

Krieger *et al.*, *Biochemistry*, 31, 4223-4231, (1992); Hook *et al.*, *J. Biol. Chem.*, 260:5991-5997, (1985); and Tezapsidis *et al.*, *J. Biol. Chem.*, 270:13285-13290, (1995), which are incorporated herein by reference).

The substantially pure vesicles can be obtained from the tissue homogenates or lysed cells using known methods (see *Current Protocols in Protein Science*, Vol. 1 and 2, Coligan *et al.*, Ed., John Wiley and Sons, Pub., Chapter 4, pp. 4.0.1-4.3.21, (1997)). For example, substantially pure secretory vesicles can be isolated using discontinuous sucrose gradient centrifugation methods (see Krieger *et al.*, *ibid.*; and Yasothornsrikul *et al.*, *J. Neurochem.* 70, 153-163, (1998)). Vesicles also can be isolated using metrizamide gradient centrifugation (Toomin *et al.*, *Biochem. Biophys. Res. Commun.*, 183:449-455, (1992); and Loh *et al.*, *J. Biol. Chem.*, 259:8238-8245, (1984), or percoll gradient centrifugation (Russell, *Anal. Biochem.*, 113:229-238, (1981). If desired, capillary electrophoresis methods can be used to isolate individual vesicles (Chie *et al*, *Science*, 279:1190-1193, (1998)). Other methods, including differential centrifugation, fluorescence-activated sorting of organelles, immunoabsorption isolation, elutriation centrifugation, gel filtration, magnetic affinity chromatography, protein chromatographic resins, agarose gel electrophoresis, and free flow electrophoresis methods, also can be used to obtain substantially pure vesicles. The references cited in this paragraph are incorporated by reference.

The purity of the secretory vesicle preparation can be assayed for by morphological or chemical means. For example, vesicles can be identified by their characteristic morphology as observed by electron microscopy. The vesicles can be prepared for electron microscopy using various methods including ultra-thin sectioning and freeze-fracture methods. Vesicles also can be identified by the presence of a characteristic neurotransmitter or hormone present in such vesicles such as the (Met)enkephalin, catecholamines, chromogranins, neuropeptide Y, vasoactive intestinal peptide, somatostatin, and galanin found in chromaffin vesicles (Hook and Eiden, *FEBS Lett.* 172:212-218, (1984); Loh *et al., J. Biol. Chem.* 259:8238-8245, (1984); Yasothornsrikul *et al., J. Neurochem.* 70:153-163, (1998), which are incorporated herein by reference). The presence of the characteristic chemical compound can be determined by various means including, for example, by radioactive, fluorescent, cytochemical, immunological assays, or mass spectrometry methods. More specifically, such assays include radioimmunoassays, western blots or MALDI mass spectrometry. In addition, vesicles can be assayed using light and electron microscopic methods, fluorescent cell activated cell sorter methods, density gradient fractionation methods, immunoabsorption methods, or biochemical methods.

The activity of the secretases can be preserved while the vesicles are purified using known methods. For example, the vesicles can be obtained at a low temperature (e.g. 4°C) and frozen (e.g. -70°C) prior to assaying for secretase activity. The activity can also be preserved by obtaining the vesicles in the presence of a stabilizing

agent known to preserve protease activity (see *Enzymes*, Dixon *et al.*, Eds., Academic Press, Pub., pp. 11-12, (1979), and *Current Protocols in Protein Science*, , Vol. 1 and 2, Coligan *et al.*, Ed., John Wiley and Sons, Pub., Chapter 4, pp. 4.5.1-4.5.36, (1997), which are incorporated herein by reference). Known stabilizing agents include proteins, detergents and salts, such as albumin protein, CHAPS, EDTA, glycerol, and NaCl. Reducing agents are also known to preserve protein function and can be used (see Voet *et al.*, *Biochemistry*, John Wiley and Sons, Pub., pp. 382-388 and 750-755, (1990), which is incorporated herein by reference). Known reducing agents include, for example, β-mercaptoethanol, DTT, and reduced glutathione (see Example VIII).

So that secretases within the vesicles are accessible to an APP substrate in an incubation solution, the vesicles are permeablized (see Voet *et al.*, *Biochemistry*, John Wiley and Sons, Pub., pp. 284-288, (1990); and Krieger et al., *ibid.*, which are incorporated herein by reference). Permeabilizing can result in a continuum of affects on the vesicle ranging from the formation of one or more holes in the membrane to complete lysis of the membrane. Vesicles can be permeablized, for example, by contact with a detergent or a disruptive agent such as CHAPS, sodium dodecyl sulfate, sodium cholate, digitonin, Brij 30 or TRITON X-100. Vesicles can be lysed, for example, by freeze-thawing, especially in a potassium chloride solution, by suspension in a hypoosmotic solution or by mechanical means such as sonication.

The permeablized vesicles are incubated with an APP substrate under appropriate conditions for cleavage of the APP substrate by a secretase. Various incubation conditions are known to affect protease cleavage. For example, the pH of the interior of chromaffin vesicles is acidic and some proteases in those vesicles are known to only function in an acidic incubation solution (Pollard *et al., J. Biol. Chem.* 254:1170-1177, (1979); and Hook *et al., FASEB J.* 8:1269-1278, (1994)). Thus, a condition for cleavage of the APP substrate includes an incubation solution having a pH of about 7.0 or less. But secretases in vesicles are released by cells into the extracellular environment, which can have a neutral or basic pH. Thus, vesicles can contain secretases that function at the neutral or basic pH of the extracellular environment and, as such, that pH can also be an appropriate condition. The pH of the incubation solution can be adjusted using known buffers (see Voet *et al., Biochemistry*, John Wiley and Sons, Pub., pp. 35-39, (1990)). Such buffers include, for example, citric acid, sodium phosphate, MES, HEPES and Tris-HCl buffers. The pH of the incubation solution can be determined using known methods such as, pH color indicators in liquid or paper formats, or pH meters. Examples III, IV, VIII, and IX show that the pH of the incubation solution can affect the activity of secretases.

Other conditions that affect the cleavage include the incubation temperature and incubation time. Proteolytic activity is a function of temperature with excessively low or high temperatures resulting in no detectable activity. An incubation temperature thus is any temperature which allows detection of a cleaved APP substrate. Usually an

incubation temperature of about 30° to 45°C, with a typical temperature of about 35° to 40°C, and often a temperature of about 37°C is used. Although not required, a constant temperature during the incubation time is preferred and can be achieved using an incubator, water bath or other known means. An insufficient or excessive incubation time results in too little production or too much degradation of the product to be detected. The incubation time for cleavage of an APP substrate is that amount of time which allows cleavage of the APP substrate to be detected. A preferred incubation time allows the cleavage of an APP substrate to go to completion, for example, in about 2 to 8 hours.

The proteolytic activity of a secretase is determined by the cleavage of an APP substrate. An "APP substrate" as used herein is a compound having a stereochemical structure that is the same as, or a mimic of, an amino acid sequence in an APP protein, an Aß peptide, an α-APP fragment or a 10 kDa fragment recognized by a secretase. Thus, an APP substrate for detecting a ß- or γ-secretase includes, for example, the APP_{695}, APP_{714}, APP_{751}, and APP_{771} proteins and an APP substrate for detecting an α-secretase includes, for example, those proteins and the Aβ peptides. As discussed above, such proteins, peptides and fragments have been isolated and characterized (Kang *et al.*, *Nature* 325:733-736, (1987); Kitaguchi *et al.*, *Nature* 331:530-532, (1988); Ponte *et al.*, *Nature* 331:525-527, (1988); Tanzi *et al.*, *Nature* 331, 528-530, (1988); Tanzi *et al.*, *Science* 235:880-884, (1987), Glenner *et al.*, *Biochem. Biophys. Res. Commun.* 120, 885-890, (1984); Masters *et al.*, *Proc. Natl. Acad. Sci. USA* 82: 4245-4249, (1985); Selkoe *et al.*, *J. Neurochem.* 146: 1820-1834, (1986); Selkoe, *J. Biol.*

Chem. 271:18295-18298, (1996); Mann *et al., Amer. J. Pathology* 148: 1257-66, (1996); Masters *et al., Proc. Natl. Acad. Sci. USA* 82: 4245-4249, (1985); Selkoe *et al., J. Neurochem.* 146: 1820-1834, (1986); Selkoe, *J. Biol. Chem.* 271:18295-18298, (1996); and Mann *et al., Amer. J. Pathology* 148: 1257-66, (1996)).

Such APP substrates can be produced by various methods known in the art (Knops *et al., J. Biol. Chem.* 266:7285-7290, (1991); Hines *et al., Cell. Molec. Biol. Res.* 40:273-284, (1994)). For example, the APP proteins can be made using recombinant technology and cloning the cDNA that encodes the proteins into a suitable expression system. An APP protein cDNA can be obtained, for example, by screening a human brain cDNA library with a DNA probe consisting of an oligonucleotide complementary to the APP protein cDNA, a PCR-generated DNA fragment of the APP protein cDNA, or a DNA fragment of the APP protein cDNA from an expressed sequence tagged (EST) database. Expression systems to produce APP proteins include, for example, *E.* coli., baculovirus-infected insect cells, yeast cells, and mammalian cells. Alternatively, such proteins can be produced using *in vitro* methods, which transcribe and translate the RNA that encodes these proteins to produce the proteins. An APP so produced can be purified using methods such as described herein or otherwise known in the art.

An APP substrate is also an APP substrate-fusion substrate, in which a protein or peptide is attached to an APP substrate for the purpose of facilitating the isolation of the APP substrate. Proteins or polypeptides that facilitate purification include, for example,

maltose-binding protein and multi-histidine polypeptides attached to the amino or carboxyl terminal end of the APP substrate. Thus, an example of an APP-fusion substrate is a multi-histidine polypeptide attached to the carboxyl terminus of an APP_{695}, APP_{714}, APP_{751}, or APP_{771} protein. Such APP-fusion substrates can be produced using known methods such as by expression of the cDNA that encodes the APP-fusion substrate in a suitable expression system or *in vitro* translation of the encoding RNA. The APP-fusion substrates so produced can be purified by affinity binding to a column, such as by amylose, nickel or anti-APP antibody column chromatography.

Peptides are also known to function as protease substrates (see Sarath *et al.*, *Protease assay methods*, In: *Proteolytic Enzymes, A Practical Approach*, R.J. Beynon and J.S. Bond, Eds., Oxford University Press, Pub., Chapter 3, pp 25-55, (1989). Often such a peptide substrate will contain the amino acids at a scissile bond in a precursor protein (see Benyon *et al.*, *The Schecter and Berger Nomenclature for Protease Substrates*, In: *Proteolytic Enzymes, A Practical Approach*, R.J. Beynon and J.S. Bond, Eds., Oxford University Press, Pub., especially, Appendix 1, pp 231, (1989); and Barrett, *An Introduction to the Proteinases*, In: *Proteinase Inhibitors*, A.J. Barrett and G. Salvesen, Eds., Elsevier, Pub., Chapter 1, pp. 3-18, (1986)). A scissile bond is the peptide bond cleaved by a protease in a precursor protein. The amino acid on the amino terminal side of the scissile bond is often called the P1 amino acid and that on the carboxyl terminal side the P1' amino acid.

A protease that cleaves a scissile bond binds the P1 and P1' amino acids. For some proteases, the P1 amino acid is the primary determinant for protease binding to the precursor protein. For example, the protease trypsin is known to have a marked preference for binding basic P1 amino acids. Peptide substrates often contain the amino acids attached to the amino terminal side of a P1 amino acid because those amino acids can influence the determinant effect of the P1 amino acid.

An APP substrate also includes a peptide having an amino acid sequence recognized by a secretase containing a P1 or P1' amino acid, or both, of a scissile bond in an APP protein and one or more of the amino acids in the APP protein adjacent to either the P1 or P1' amino acids or both. For example, as shown in Figure 1, a β-secretase scissile bond is between the P1 amino acid methionine (Met or M) and the P1' amino acid aspartic acid (Asp or A). A ß-secretase recognition site thus includes, for example, a Met-Asp substrate.

Often an APP substrate is a peptide containing the P1 and P1' amino acids of a scissile bond in an APP protein and the one or two amino acids in the APP protein attached to the amino terminal side of the P1 amino acid. For example, as shown in Figure 1, a lysine (Lys or K) is attached to the amino terminal side of the P1 amino acid of the ß-secretase scissile bond and a valine (Val or V) is attached to the amino terminal side of the Lys. Thus, an APP substrate for the ß-secretase includes the Lys-Met-Asp and Val-Lys-Met-Asp (SEQ. ID NO.:1) substrates.

The APP substrate peptide containing the P1 and P1′ amino acids of a scissile bond in an APP protein can be determined for the γ-secretase and the α-secretase in the same manner. For example, as shown in Figure 1, the γ-secretase scissile bond of the $A\beta_{1-40}$ peptide has a Val P1 amino acid, an isoleucine (Ile or I) P1′ amino acid, a second Val attached to the amino terminal side of the P1 amino acid and a glycine (Gly or G) attached to the amino terminal side of the second Val. As such, the γ-secretase recognition site for the $A\beta_{1-40}$ peptide includes, for example, the Val-Ile, Val-Val-Ile and Gly-Val-Val-Ile (SEQ ID NO.:2) substrates. The γ-secretase recognition site for the $A\beta_{1-42}$ peptide thus includes, for example, the Ala-Thr, Ile-Ala-Thr and Val-Ile-Ala-Thr (SEQ ID NO.:3) substrates and that the g-secretase recognition site for the $A\beta_{1-43}$ peptide includes, for example, the Thr-Val, Ala-Thr-Val, and Ile-Ala-Thr-Val (SEQ ID NO.:4) sequences. Similarly, the α-secretase recognition site can be determined from the amino acids in the APP protein surrounding the α-secretase scissile bond.

Proteases are known to have endoprotease, aminopeptidase, or carboxypeptidase activity, or a combination of these activities (see Sarath *et al.*, *ibid.*). A protease having endoprotease activity cleaves the peptide bond between two adjacent amino acids, neither of which is a terminal amino acid, or, as discussed below. between a non-terminal amino acid and a terminal blocking group. A protease having aminopeptidase activity only cleaves the peptide bond between the amino terminal amino acid and its adjacent amino acid. A protease having carboxypeptidase

activity only cleaves the peptide bond between the carboxyl terminal amino acid and its adjacent amino acid.

Secretases of the invention also can have endoprotease, aminopeptidase, or carboxypeptidase activity, or a combination of these activities. For example, an Aβ peptide can be cleaved from an APP protein directly by endoprotease cleavage of the scissile bonds at both ends of the Aβ peptide. But an Aβ peptide also can be produced by an endoprotease cleavage of a scissile bond distal to the terminal amino acids of the Aβ peptide followed by aminopeptidase or carboxypeptidase cleavage of the amino acids flanking the terminal amino acids of the Aβ peptide.

An APP substrate often contains one or more amino terminal or carboxyl terminal blocking groups, which prevent aminopeptidase or carboxypeptidase cleavage, respectively (see Sarath *et al., ibid.*). But an amino terminal blocking group does not prevent carboxypeptidase and, conversely, a carboxyl terminal blocking group does not prevent aminopeptidase cleavage. As such, an APP substrate can often contain both an amino terminal and carboxy terminal blocking group to prevent both aminopeptidase and carboxylpeptidase cleavage. An APP substrate containing both blocking groups can only be cleaved, if at all, by a secretase having endoprotease activity.

Blocking groups and methods of making substrates containing blocking groups are known in the art (see, for example, *Methods in Enzymology*, Vol. 244, "Proteolytic Enzymes," A.J. Barrett, Ed., Chapters 46, 47, and 48, (1994); and Green and Wuts, *Protective Groups in Organic*

Synthesis, John Wiley and Sons, Pub., (1991) which are herein incorporated by reference). Amino terminal blocking groups include, for example, acyl (Ac), benzoyl (Bz), succinyl (Suc), carbobenzoxy (Z), *p*-bromocarbobenzoxy, *p*-chlorocarbobenzoxy, *p*-methoxycarbobenzoxy, *p*-methoxyphenylazocarbobenzoxy, *p*-nitrocarbobenzoxy, *p*-phenylazocarbobenoxy, tert-butoxycarbonyl (Boc), benzoyl and the like. Carboxyl blocking groups include, for example, aminomethylcourmarinamide (MCA), the diazomethanes, the *p*-nitroanlide (*p*NA), *p*NA•Tosylate, 2-naphthylamine, the acyloxymethanes, including the (benzoyloxy)methanes, (alkyloxy)methanes, the N,O-diacyl hydroxamates, including the N-aminoacyl-O-4-nitrobenzoyl hydroxamates, esters, including methyl, ethyl and nitrophenyl esters, chloromethylketone and the like.

Although endoproteases do not cleave terminal amino acids, endoproteases can cleave a carboxyl terminal blocking group attached via a peptide bond to the carboxyl terminal amino acid of a peptide containing two or more amino acids (see Sarath *et al.*, *ibid.*). If the carboxyl terminal amino acid is the P1 amino acid of a scissile bond in a precursor protein, the carboxyl terminal blocking group mimics the P1′ amino acid in that scissile bond. Moreover, endoprotease cleavage of the carboxyl terminal blocking group mimics the cleavage of the corresponding scissile bond in the precursor protein. Such carboxyl terminal blocking groups include, for example, MCA, *p*NA, and *p*NA•Tosylate. An APP substrate which contains such a carboxyl terminal blocking group and an amino terminal blocking group can only be cleaved, if at all, by an endoprotease.

An APP substrate includes a secretase recognition site that contains a P1 amino acid of a scissile bond in an APP protein and a carboxyl terminal blocking group which replaces the P1′ amino acid in that scissile bond. The APP substrate also contains one or more of the amino acids in the APP protein attached to the amino terminal side of the P1 amino acid. Such an APP substrate will bind a secretase which binds the corresponding scissile bond in the APP protein because the substrate contains the P1 amino acid, the primary determinant for that binding. For example, a β-secretase recognition site containing such a carboxyl terminal blocking group includes, for example, the Val-Lys-Met-MCA substrate in which the MCA group replaces the Asp P1′ amino acid of the ß-secretase scissile bond. Endoprotease cleavage of the Met-MCA peptide bond in that substrate is equivalent to endoprotease cleavage of the scissile bond Met-Asp of the ß-secretase recognition site in the APP protein. Similarly a γ-secretase recognition site for the $A\beta_{1-40}$ peptide includes, for example, the Gly-Val-Val-*p*NA substrate in which the *p*NA group replaces the Ile P1′ amino acid of the corresponding γ-secretase recognition site and endoprotease cleavage of the *p*NA group is equivalent to endoprotease cleavage of the corresponding scissile bond in the APP protein. Similar substrates are envisioned for the γ-secretase recognition site for the $A\beta_{1-42}$, and $A\beta_{1-43}$ peptides and the α-secretase recognition site.

The APP substrate as discussed in the paragraph above can also contain an amino terminal blocking group. Only those secretases having endoprotease activity will cleave that APP substrate and the endoprotease cleavage of

the substrate will mimic that which occurs in the APP protein. Examples of such APP substrates include, but are not limited to, Z*Lys-Met-MCA, Z*Val-Lys-Met-MCA, Z*Val-Val-MCA, Z*Gly-Val-Val-MCA, Z*Ile-Ala-MCA, Z*Val-Ile-Ala-MCA, Z*Ala-Thr-MCA, and Z*Ile-Ala-Thr-MCA substrates. In these examples, Z represents the amino terminal blocking group carbobenzoxy and the star (*) indicates a non-peptide bond between the Z and the adjacent amino acid. The MCA represents the carboxyl terminal blocking group aminomethylcourmarinamide and the dashes (-) represent peptide bonds between the MCA and the adjacent amino acid or between adjacent amino acids.

Secretases having aminopeptidase activity can be assayed for using an APP substrate that contains an amino acid of a secretase recognition site and a carboxyl terminal blocking group. Examples of such APP substrates include Met-MCA and Lys-MCA substrates from the β-secretase recognition site. However, if such substrates contain only one amino acid, the substrate cannot be cleaved by an endoprotease because the only amino acid is an amino terminal amino acid. The Met-MCA and Lys-MCA substrates were used to identify β-secretase aminopeptidase secretase activities (see Example IV).

An APP substrate often contains one or more labels that facilitate detection of the substrate or the APP derived product. A label can be an atom or a chemical moiety. Substrates containing a label can be made by methods known in the art. For example, radioactive atoms such as ^{3}H or ^{32}P can be attached to an APP substrate to detect an APP derived product. Also, heavy atoms or atom

clusters such as, gold clusters can be attached. Moreover, fluorescent molecules such as, fluorescein, rhodamine, or green fluorescent protein, can be attached. A label can have more than one function. For example, the MCA is a carboxyl blocking group that is not fluorescent when bound in an APP substrate, is an APP derived product when cleaved by an endoprotease from a substrate, and is a label because, when MCA is cleaved from the substrate, it becomes fluorescent aminomethylcourmarinamide (AMC or free MCA) which is detectable (Azaryan and Hook, *Arch. Biochem. Biophys.* 314:171-177, (1994); and Azaryan *et al., J. Biol. Chem.* 270:8201-8208, which are incorporated herein by reference).

Cleavage of an APP substrate can be detected by the presence of an APP derived product. The term "APP derived product" refers to a protein, polypeptide, peptide or chemical moiety produced by proteolytic cleavage of an APP substrate. An APP derived product includes, for example, an Aβ peptide, an α-APP fragment, a 10 kDa fragment, and AMC. A chemical moiety is the blocking group or label discussed above.

An APP derived product or an APP protein can be qualitatively or quantitatively detected using various methods. For example, these products or proteins can be detected by an immunoassay using antibodies such as monoclonal or polyclonal antibodies against the $A\beta_{1-40}$ peptide, $A\beta_{1-42}$ peptide, $A\beta_{1-43}$ peptide, the amino terminal or the carboxyl terminal regions of the APP proteins and the APP proteins. Such antibodies are commercially available, for example, from PENINSULA LABORATORIES, Belmont, CA;

CALBIOCHEM, San Diego, CA; QCB, Hopkinton, MA; or IMMUNODYNAMICS, La Jolla, CA.

SDS-PAGE electrophoresis and western blots can also be used to detect an APP derived product and an APP protein (see Example XII). Other methods include detecting a label on or from the APP derived product or APP protein such as a radioactive or fluorescent label. Microsequencing, amino acid composition analysis, or mass spectrometry analysis can also be used (see Example XV). Chromatography separation methods based on physical parameters such as molecular weight, charge, or hydrophobicity can be used. Preferred chromatography methods include high pressure liquid chromatography (HPLC) and automated liquid chromatography (FPLC, PHARMACIA, Piscataway, NJ). Spectrophotometric detection methods such as UV absorbance at 280 nm or 210-215 nm, can also be used. Known light or electron microscopic methods as well as fluorescent activated cell sorter methods also can be used to detect APP derived products and APP proteins. The quantitative fluorescence analysis using a fluorometer was used to detect the fluorescent AMC product produced by β-secretase cleavage of the Z*Val-Lys-Met-MCA, Met-MCA, and Lys-MCA (see Examples III, IV, VIII, and IX).

Figure 2 shows the endoprotease cleavages that can occur in an APP substrate containing a β-secretase recognition site and amino and carboxyl terminal blocking groups and how such cleavages can be detected. In that figure, the three endoprotease cleavages of the APP substrate Z*Val-Lys-Met-MCA are shown (#1, #2, and #3). The Met-MCA bond (#3) mimics the scissile bond between the P1

and P1' amino acids Met and Asp in the APP protein at the amino terminal end of the Aβ peptide. Endoprotease cleavage of the Met-MCA bond in the substrate is equivalent to endoprotease cleavage of the APP protein. That cleavage in the APP protein would produce directly the amino terminal end of the Aβ peptide. That cleavage can be detected by the characteristic fluorescence produced by AMC (free MCA).

Endoprotease cleavage of the Lys-Met bond (#2) and the Val-Lys bond (#3) in the Z*Val-Lys-Met-MCA substrate produces a Met-MCA and Lys-Met-MCA peptide, respectively. The corresponding endoprotease cleavages in the APP proteins would be distal to the amino terminal end of the Aβ peptide. However, such distal endoprotease cleavages can occur *in vivo* because, as discussed above, such cleavages followed by aminopeptidase cleavage of the flanking amino acids can produce the amino terminal end of the Aβ peptide.

The Met-MCA and Lys-Met-MCA peptides are not fluorescent, but contain free amino terminal amino acids, which an aminopeptidase can cleave to liberate AMC. To insure that the endoprotease cleavages of the Lys-Met and the Val-Lys bonds are detected, an aminopeptidase can be added to an incubation solution to liberate AMC from the Met-MCA and Lys-Met-MCA peptides. Known aminopeptidases include, for example, aminopeptidase M and methionine aminopeptidase (*Mammalian Proteases, a Glossary and Bibliography*, J.K. Mcdonald and A.J. Barrett, Ed., Academic Press, Pub., p. 23-99, (1986)). In this manner, all the endoprotease cleavages of the Z*Val-Lys-Met-MCA substrate can be detected.

Such methods were used to identify endoprotease activity of one or more β-secretases in substantially purified vesicles (see Examples III, VIII, and IX). In particular, a secretase in substantially purified vesicles was shown to cleave the Z*Val-Lys-Met-MCA substrate at a pH of about 4.0 to about 5.5 using these methods.

METHODS OF ISOLATING A SECRETASE

The present invention also is directed to a method of isolating a secretase using the assay described above to determine the proteolytic activity of a secretase and isolating that secretase from substantially purified vesicles. Generally, the isolation is done by assaying the activity of the secretase after each step in the isolation. If necessary, the activity can be preserved during the isolation procedure using methods such as those described above, including, for example isolating the secretase at a low temperature (e.g. 4°C), or in the presence of one or more of the above-described reducing or stabilizing agents.

The secretase is isolated based on its physical properties. For example, a secretase can be isolated based on its molecular weight and size using gel filtration chromatography such as, Sephacryl S200, Sephadex G150, Superose 6 or 12, and Superdex 75 or 200 resin chromatography. A secretase can also be isolated based on its charge using ion-exchange chromatography such as DEAE-Sepharose, CM Sephadex, MonoQ, MonoS and MonoP resin chromatography. In addition, a secretase can be isolated based on its water solubility using hydrophobicity chromatography such as phenyl Sepharose, butyl Sepharose and

octyl Sepharose resin chromatography. Interactions between the secretase and hydroxyapatite can also be used for isolation using, for example, macro-prep hydroxyapatite, and Bio-Gel HT hydroxyapatite resins.

A secretase can also be isolated based on specific biochemical properties of the secretase using affinity chromatography. For example, the secretase can be isolated using APP substrate affinity chromatography under conditions in which the secretase binds the APP substrate but does not cleave it. Glycosylated secretases can be isolated using lectin affinity chromatography such as, concanavalin A-Sepharose, lentil lectin Sepharose, wheat germ lectin Sepharose resin chromatography. The proteolytic activity of sulfhydryl groups such as those on cysteine amino acids can be used to isolate the secretases using thiol-propyl chromatography. Finally, the affinity of the secretases for specific dyes can be used for separation such as, blue-Sepharose resin chromatography. Other affinity chromatography methods include arginine-Sepharose, benzamidine Sepharose, glutathione Sepharose, lysine-Sepharose and chelating Sepharose resin chromatography. The secretases can also be isolated by non-chromatographic fractionation methods using, for example, native gel electrophoresis, analytical ultracentrifugation and differential ammonium sulfate precipitation methods (see Example XII).

Using such methods, alone or in combination, a secretase of the invention can be isolated. The term "isolated" when used in reference to a secretase means that the secretase is relatively free of other proteins, amino

acids, lipids and other biological materials normally associated with a cell. Generally, an isolated secretase constitutes at least about 50%, and usually about 70% to 80%, and often about 90 to 95% or more of the biological material in a sample. A secretase often is isolated such that it is free of other substances that affect the cleavage of an APP substrate, such as an inhibitor or activator protein. The extent to which the secretases are isolated using such methods can be determined by known protein assays. For example, the amount of protein in the resulting chromatographic fractionation can be quantitated using the Lowry method and the specific activity can be used to quantitate the isolation (see Example XIII). Alternatively, SDS-PAGE or two-dimensional gel electrophoresis and mass spectroscopy methods can be used.

After initial isolation of a secretase, antibodies specific to the secretase can be produced and secretases isolated using immunoaffinity chromatography. Such antibodies can be produced using known immunological methods including, for example, monoclonal antibody and polyclonal antibody production methods (see Haylow and Lane, *Antibodies: A Laboratory Manual*, Cold Spring Harbor Laboratory Press, (1988)).

The amino acid sequence of the secretase also can be determined after isolation of the secretase. For example, the amino acid sequence of the secretase can be determined using peptide microsequencing methods known in the art (see *"Current Protocals in Protein Science,"* Vol. 1 and 2, Coligan *et al.*, Ed., (1997), John Wiley and Sons). Alternatively, the partial amino acid sequence can be

determined from fragments of the secretase using mass spectrometry and Edman microsequencing methods (*"Current Protocols in Protein Science,"* Vol. 1 and 2, Coligan *et al.*, Ed., (1997), John Wiley and Sons). For example, the secretase can be isolated using an SDS-PAGE gel and stained with coomassie blue in the gel. The secretase in the gel can be subjected to in-gel tryptic digestion and the amount of protein determined by amino acid analysis. Tryptic peptide fragments can be separated by HPLC, and the amino acid sequence of each fragment determined by Edman microsequencing and mass spectrometry methods. The amino acid sequence of the secretase can be determined from the amino acid sequences of the peptide fragments using computer analysis of known amino acid sequences.

Based on the partial amino acid sequence of a secretase, the cDNA of the secretase can be cloned (see, for example, *Molecular Cloning, a Laboratory Manual*, Vol. 1, 2, and 3, Sambrook *et al.*, Ed., Cold Spring Harbor Laboratory Press, Pub., (1989); and *Current Protocols in Molecular Biology*, Vol. 1, 2, and 3, Ausubel *et al.*, Ed., Wiley Interscience, Pub., (1997)). Briefly, partial, cloned secretase cDNAs are obtained by reverse transcription-polymerase chain reaction methods (RT-PCR) using oligonucleotides complementary to the partial amino acid secretase sequences. The complementary oligonucleotides synthetically synthesized can contain either degenerate codons, including inosine, or be optimized for mammalian cell use. The PCR-generated DNA fragment is analyzed for nucleic acid sequences and restriction enzyme sequences, and overlapping sequences among the different PCR-generated DNA fragments are determined. Northern blot

or RT-PCR analysis using the PCR-generated cDNAs, or complementary oligonucleotides, so produced are used to determine tissues that produce mRNAs encoding the secretase. A cDNA library from such tissues is constructed and screened using the PCR-generated secretase cDNA or the complementary oligonucleotides. From such screened cDNA libraries, the cDNA sequence encoding the full-length amino acid sequence of the secretase is determined.

The cDNA of a secretase can also be obtained by generating antibodies against the partial amino acid sequences, screening cDNA expression libraries with an anti-secretase antibody, and analyzing the nucleic acid sequences of such clones. The amino acid sequence of the secretase can be deduced from the secretase cDNA sequence. The full-length cDNA can be cloned in an expression system such as in *E. coli*, Sf9 insect cells, yeast, or mammalian cell lines, and the activity of the expressed secretase determined to confirm that the cDNA encodes a functional secretase.

Another method of obtaining the cDNA of a secretase is to clone the secretase in a genetic screen for isolating the secretase cDNA using the bacteriophage l regulatory circuit, where the viral repressor is specifically cleaved to initiate the lytic phase of bacteriophage to allow detection and isolation of plaques containing the secretase cDNA(s) (Sices and Kristie, *Proc. Natl. Acad. Sci. USA* 95:2828-2833, (1988)).

The gene(s) encoding a secretase can be isolated by screening a genomic library with the cDNAs encoding the partial or full length secretase, or with the oligonucleotides that are complementary to a sequence encoding a determined secretase amino acid sequence. The nucleic acid sequence of the secretase genomic DNA is determined, and the exon/intron structure of the secretase gene is determined by comparing the DNA sequence of the gene to the nucleic acid sequence of the secretase cDNA.

Once the cDNA encoding a partial or full-length endogenous secretase is obtained from one animal species, that cDNA can be used to obtain endogenous secretases from another animal species using known methods (*Molecular Cloning, a Laboratory Manual, ibid.*; and *Current Protocols in Molecular Biology, ibid.*). For example, the cDNA encoding the partial bovine secretase can be used to obtain cDNAs encoding human secretases. Briefly, a partial or full-length bovine cDNA, or a labeled complementary oligonucleotide, is used to isolate the human secretase cDNA by screening human cDNA libraries constructed from tissues that contain secretase mRNA, determined by northern blot or RT-PCR analyses. Alternatively, the human secretase cDNA can be obtained by searching the expressed sequence tag database (EST) for human cDNA sequences similar to the bovine secretase cDNA. DNA sequencing of the resulting secretase clones can be performed to determine the nucleic acid sequence encoding the human secretase and the corresponding amino acid sequence can be deduced. The cDNA encoding the human secretase can be cloned in and expressed by a suitable expression vector and the activity of the

expressed secretase can be determined. The genes encoding the human secretase can be cloned as described herein.

The nucleic acid sequence of a secretase can also be used to produce the secretase using known recombinant methods (*Molecular Cloning, a Laboratory Manual, ibid.*; and *Current Protocols in Molecular Biology, ibid.*). The cDNA encoding the secretase can be inserted into an appropriate expression vector and the expression vector introduced into an appropriate host as described herein. Expression of the secretase by the host is stimulated by expression of a vector promotor.

METHODS OF SCREENING FOR AGENTS THAT AFFECT THE PROTEOLYTIC ACTIVITY OF A SECRETASE

Another aspect of the invention is a method of selecting an agent that alters the cleavage of an APP substrate by a secretase. Such agents, particularly those that decrease the cleavage by the β-secretase and γ-secretases or that increase the cleavage by the α-secretase, are useful for developing drugs that prevent or treat AD. Agents having divergent chemical structures can be assayed using such methods including, for example, small organic molecules that optionally contain heteroatoms or metals, amino acids, peptides, polypeptides, proteins, peptidomimetics, nucleic acids, carbohydrates, glycoproteins, lipids, and lipoproteins.

The method is based on comparing the APP substrate cleavage, or the APP protein, or APP derived product production that occurs with and without an agent. This is

achieved by determining the APP substrate cleavage or the APP protein or the APP derived product produced in a first incubation or culture solution lacking the agent and comparing that result with that which occurs in a second incubation or culture solution containing the agent. The first and second incubation or culture solutions can be different solutions or the same solution to which the agent is added or removed. The APP substrate cleavage, the APP protein, and the APP derived product can be assayed using the methods described herein. The concentration of the agent can vary due to parameters known in the art such as the hydrophobicity, charge, size and potency of the agent, but typically is about a 10^{-9} to 10^{-3} M.

Agents are selected that alter the cleavage of an APP substrate or production of an APP protein or an APP derived product. The cleavage or production is altered if the agent causes a significant change in the cleavage or production relative to that which occurs without the agent. A significant change can be determined using a variety of qualitative or quantitative methods, such as, for example, by a visual or statistical analysis of the comparison data. For example, the mean amounts of an APP derived product obtained with and without the agent can be analyzed using a two-sided Student's t-test and a $p \geq 0.02$ or greater, and preferably a $p \geq 0.05$, in that test can be indicative of a significant difference.

Often agents are screened using substantially pure vesicles as the source of the secretase. But substantially pure vesicles can contain, in addition to secretases, other substances that affect the cleavage of an APP substrate,

such as the presenilin 1 protein. Thus, a screen using such vesicles selects for agents that directly or indirectly alter the cleavage. An agent can directly affect the cleavage by, for example, inhibiting the binding of an APP substrate to a secretase. But an agent can also indirectly alter the cleavage by affecting an inhibitor or activator substance which in turn affects the activity of the secretase. For example, proteases may be present in the vesicle that produce the secretase from a precursor protein or that degrade the secretase. An agent thus can indirectly affect the secretase activity by affecting the proteases which produce or degrade the secretase. Often permeablized chromaffin vesicles and an APP protein, Aβ peptide, Z*Val-Lys-Met-MCA, Z*Gly-Val-Val-MCA, Z*Val-Ile-Ala-MCA, or Z*Ile-Ala-Thr-MCA substrate are used in the assay.

An isolated secretase, obtained as described above, can also be used to select for agents that affect the activity of the secretase. Using an isolated secretase free of other substances that affect the cleavage of an APP substrate, agents can be selected that directly affect cleavage of the APP substrate. The affect of an agent on such an isolated secretase and on substantially purified vesicles can be compared to determine the direct and indirect affects of the agent. Moreover, that comparison can be used to determine if the vesicles contain inhibitors or activators of the secretase removed during isolation of the secretase.

The protease class to which an isolated secretase belongs can be determined using agents known to selectively inhibit different classes of proteases. For example, E-64c,

cystatin, and *p*-mercuribenzoate inhibit cysteine proteases; phenylmethylsulfonyl fluoride (PMSF), soybean trypsin inhibitor, and α_1-antitrypsin inhibit serine proteases; ethylenediaminetetraacetic acid (EDTA) and 1,10-O-phenanthroline inhibit metalloproteases; and pepstatin A inhibits aspartyl proteases. (See Examples XI and XIV).

In another method, a cell containing vesicles having the proteolytic activity of a secretase is used to select for an agent. Cells containing such vesicles can be identified using the methods described above to determine the proteolytic activity of a secretase in the vesicles. The cells are cultured in a first culture solution without the agent and in a second culture solution with the agent and the production of an APP protein or an APP derived product by the cell, especially an Aβ peptide, α-APP fragment or 10 kDa fragment, in the first and second culture solution compared.

A problem with using transformed cell cultures or cell lines to select agents is that the agents may be ineffective *in vivo* because cells in culture can process a protein in a manner unrelated to that which occurs *in vivo*. Thus, agents that affect the processing of such cells are ineffective because the processing that they affect does not occur *in vivo*. The cell based method provided in the present invention avoids this problem by selecting cells determined to contain vesicles that have the proteolytic activity of a secretase. As such, the method insures that the cells process the APP protein in the cell organelle in which that processing occurs *in vivo*.

A cell used in this method can be obtained from a variety sources. For example, disassociated cells maintained in a primary culture can be used in the method. Such disassociated cells can be maintained in a primary culture using known methods (see, for example, Hook *et al.*, *ibid.*; and Tezapsidis *et al.*, *ibid.*). Disassociated cells have the advantage of retaining many of the functional characteristics that they have in the tissue that they are obtained from. But primary cultures of disassociated cells generally die after a period of time. Cell lines, transformed cells and cloned cells, on the other hand, have the advantage of being immortal. But such cells are known to often abnormally process proteins. As such, it is particularly important to use immortalized cells that are determined to contain vesicles in which the proteolytic activity of a secretase occurs so as to insure that the cells are processing the APP protein in the same manner as *in vivo*. Various cell transformation methods can be used to obtain such cells (see for example, Alarid *et al.* *Development*, 122(10):3319-29, (1996); and Schecter *et al.*, *Neuroendocrinology*, 56(3):300-11, (1992), which are incorporated herein by reference). A chromaffin cell, either obtained by disassociation or by transformation, is often used in this method.

In the cell based assay of the present invention, the agent is often present when the cells are producing an APP derived product because some agents are known to only affect a protease in a cell when the protease is producing a product. For example, agents are known to inhibit enkephalin production in chromaffin cells only when the chromaffin cells are actively producing enkephalin

(Tezapsidis *et al.*, *ibid.*). Various methods can induce cells to produce proteolytically processed peptides in vesicles. For example, proteolytic processing can be induced by exocytosis. Exocytosis can be induced by various means including, for example, by increasing the extracellular potassium chloride concentration or by binding nicotinic cholinergic receptors on cells with nicotine. Proteolytic processing of the Aβ peptides can also be induced by stimulating protein kinase with phorbol esters (Koo, *Molec. Medicine*, 3:204-211, (1997); and LeBanc *et al.*, *J. Neurosci.*, 18:2908-2913, (1998)).

For example, as shown in Example VII, chromaffin cells can be induced to produce an Aβ peptide by culturing the cells in potassium chloride (about 5 to 500 mM), nicotine (about 10^{-3} to 10^{-6} M), or phorbol ester (about 10^{-3} to 10^{-6} M) for a sufficient amount of time to stimulate production (about 1 to 72 hours for the nicotine and potassium chloride and about 12 to 96 hours for the phorbol ester). During active production of the Aβ peptide by the cells, an agent is incubated with the chromaffin cells under appropriate conditions and for an appropriate amount of time (e.g. about 2 to 8 hours). The cells can then be lysed and the production of an Aβ peptide with and without the agent compared. To facilitate that comparison, a protease inhibitor such as, chymostatin, leupeptin, and soybean trypsin inhibitor (STI), can be added when cells are lysed to prevent non-specific digestion of the Aβ peptide by non-specific proteases released by cell lysis.

The cell based assay can be used to select an agent that affects cell expression. For example, the expression of a nucleic acid that encodes a secretase can be tested in such an assay. Inhibitors of gene transcription, such as actinomycin D or an antisense nucleic acid, or agents that modify protein transcription factors that regulate gene expression, such as steroids, also can be tested. The cell based assay can also be used to select agents that affect protein processing, including those affecting RNA splicing, RNA polyadenylation, RNA editing, protein translation, signal peptidase processing, protein folding including chaperone-mediated folding, disulfide bond formation, glycosylation, phosphorylation, covalent modification including methylation, prenylation, and acylation, and association with endogenous protein factors that modify secretase activity.

Agents found to alter cleavage of an APP substrate can be evaluated *in vivo* using transgenic AD animal models. Transgenic animal models have been developed in which the animals have brain amyloid plaques containing Aß peptides and, in some models, exhibit cognitive deficits such as excessive memory loss. Exemplary transgenic animals include mice that contain the Indiana mutation of the human APP cDNA under the control of the PDGF promoter (Johnson-Wood *et al.*, *Proc. Natl. Acad. Sci., USA*, 94:1550-1555, (1997)). These mice express increased levels of brain Aß peptides and amyloid plaques and show cognitive deficits. Another exemplary transgenic animal is a mouse strain containing the Swedish mutation of the human APP-695 cDNA with the hamster PrP promoter (Hsiao, *J. Neural Transmission*, 49:135-144,

(1997)). These mice express increased levels of brain Aß peptides, have amyloid plaques and are memory impaired.

The invention also provides a method of decreasing production of an Aβ peptide by an individual affected with a condition that is associated with aggregation of the Aβ peptide into amyloid plaques by administering to the affected individual an effective amount of the agent selected by the methods described herein, thereby decreasing production of the Aβ peptide by the affected individual.

The invention further provides a method of reducing the severity of a condition associated with an activity of cathepsin B by administering an effective amount of an agent selected by the method disclosed herein to the affected individual, thereby reducing the severity of the condition associated with an activity of cathepsin B in the affected individual. In a related yet disitnct embodiment, the invention provides a method of reducing the severity of a condition associated with an activity of cathepsin L by administering an effective amount of an agent selected by the method disclosed herein to the affected individual, thereby reducing the severity of the condition associated with an activity of cathepsin L in the affected individual.

Also provided by the present invention is a method of reducing the severity of a condition associated with an activity of cathepsin B and cathepsin L comprising administering an effective amount of an agent selected by administering an effective amount of an agent selected by the method disclosed herein to the affected individual, thereby reducing the severity of the condition associated

with an activity of cathepsin B and cathepsin L in the affected individual.

In a further embodiment, the invention provides a method of decreasing production of an Aβ peptide by an individual affected with a condition that is associated with aggregation of the Aβ peptide into amyloid plaques by administering to the affected individual an effective amount of the agent that inhibits an activity of cathepsin B, thereby decreasing production of the Aβ peptide by the affected individual.

In a related yet distinct embodiment, the invention provides a method of decreasing production of an Aβ peptide by an individual affected with a condition that is associated with aggregation of the Aβ peptide into amyloid plaques comprising administering to the affected individual an effective amount of the agent that inhibits an activity of cathepsin L, thereby decreasing production of the Aβ peptide by the affected individual.

Also provided by the present invention is a method of decreasing production of an Aβ peptide by an individual affected with a condition that is associated with aggregation of the Aβ peptide into amyloid plaques by administering to the affected individual an effective amount of the agent that inhibits an activity of cathepsin B and cathepsin L so as to decrease the production of the Aβ peptide by the affected individual.

The agents administered in the methods provided by the present invention can be administered to an individual affected with a condition as described herein and in need of the treatment. Agents can be administered to such animals using methods known in the art, particularly those methods that result in the agent traversing the blood brain barrier. For example, such agents can be administered by direct injection into the central nervous system or by administration with a minipump. Agents that naturally traverse the blood brain barrier can be systematically administered by intravenous, subcutaneous, or oral routes. Such agents can be administered in effective doses which for example can range from 0.001 to 10 mg/kg body weight. Agents can be administered prophylactically or therapeutically in single or multiple dose schedules.

An agent identified by the invention method and useful for treatment of a condition condition associated with aggregation of the Aβ peptide into amyloid plaques is administered in an effective amount. Such an effective amount generally is the minimum dose necessary to achieve the desired prevention or reduction in severity of one or more symptoms of a condition, for example, that amount roughly necessary to reduce the severity of one or more symptoms associated with Alzheimer's Disease. Such a dose generally is in the range of 0.1-1000 mg/day and can be, for example, in the range of 0.1-500 mg/day, 0.5-500 mg/day, 0.5-100 mg/day, 0.5-50 mg/day, 0.5-20 mg/day, 0.5-10 mg/day or 0.5-5 mg/day, with the actual amount to be administered determined by a physician taking into account the relevant circumstances including the severity and type of condition, the age and weight of the patient, the patient's general

physical condition, and the pharmaceutical formulation and route of administration. The dosage of an agent of the invention required to be therapeutically effective also will depend, for example, on previous or concurrent therapies. The appropriate amount considered to be an effective dose for a particular application of the method can be determined by those skilled in the art, using the guidance provided herein. For example, the amount can be extrapolated from in vitro or in vivo assays as described previously. One skilled in the art will recognize that the condition of the patient can be monitored throughout the course of therapy and that the amount of the agent that is administered can be adjusted accordingly.

A pharmaceutical composition containing an agent identified by the invention methods and useful in the therapeutic methods of the invention can be administered to a subject by a variety of means depending, for example, on the type of condition to be treated, the pharmaceutical formulation, and the history, risk factors and symptoms of the subject. Routes of administration suitable for the methods of the invention include both systemic and local administration. As non-limiting examples, a pharmaceutical composition useful for preventing or reducing the severity of a condition can be administered orally; parenterally; by subcutaneous pump; by dermal patch; by intravenous, intra-articular, subcutaneous or intramuscular injection; by topical drops, creams, gels or ointments; as an implanted or injected extended release formulation; by subcutaneous minipump or other implanted device; by intrathecal pump or injection; or by epidural injection. Depending on the mode of administration, the agent can be incorporated in any

pharmaceutically acceptable dosage form such as, without limitation, a tablet, pill, capsule, suppository, powder, liquid, suspension, emulsion, aerosol or the like, and can optionally be packaged in unit dosage form suitable for single administration of precise dosages, or sustained release dosage forms for continuous controlled administration.

A method of the invention can be practiced by peripheral administration of the agent, or a pharmaceutically acceptable salt, ester, amide, stereoisomer or racemic mixture thereof. As used herein, the term peripheral administration means introducing the agent into a subject outside of the central nervous system. Peripheral administration encompasses any route of administration other than direct administration to the spine or brain. Peripheral administration can be local or systemic.

For applications directed to the central nervous system a therapeutic agent identified by the invention methods can be administered in a formulation that can cross the blood-brain barrier, for example, a formulation that increases the lipophilicity of the therapeutic agent. For example, the therapeutic agent identified by the invention methods can be incorporated into liposomes (Gregoriadis, Liposome Technology, Vols. I to III, 2nd ed. (CRC Press, Boca Raton FL (1993)). Liposomes, which consist of phospholipids or other lipids, are nontoxic, physiologically acceptable and metabolizable carriers that are relatively simple to make and administer.

A therapeutic agent identified by the invention methods can also be prepared as nanoparticles. Adsorbing peptide compounds onto the surface of nanoparticles has proven effective in delivering peptide drugs to the brain (see Kreuter et al., Brain Res. 674:171-174 (1995)). Exemplary nanoparticles are colloidal polymer particles of poly-butylcyanoacrylate with a therapeutic agent identified by the invention methods adsorbed onto the surface and then coated with polysorbate 80.

Image-guided ultrasound delivery of a therapeutic agent identified by the invention methods through the blood-brain barrier to selected locations in the brain can be utilized as described in U.S. Patent No. 5,752,515. Briefly, to deliver a therapeutic agent identified by the invention methods past the blood-brain barrier a selected location in the brain is targeted and ultrasound used to induce a change detectable by imaging in the CNS (CNS) tissues and/or fluids at that location. At least a portion of the brain in the vicinity of the selected location is imaged, for example, via magnetic resonance imaging (MRI), to confirm the location of the change. A therapeutic agent identified by the invention methods and introduced into the patient's bloodstream can delivered to the confirmed location by applying ultrasound to effect opening of the blood-brain barrier at that location and, thereby, to induce uptake of the therapeutic agent.

In addition, polypeptides called receptor mediated permeabilizers (RMP) can be used to increase the permeability of the blood-brain barrier to molecules such as therapeutic agents or diagnostic agents as described in U.S.

Patent Nos. 5,268,164; 5,506,206; and 5,686,416. These receptor mediated permeabilizers can be intravenously co-administered to a host with molecules whose desired destination is the cerebrospinal fluid compartment of the brain. The permeabilizer polypeptides or conformational analogues thereof allow therapeutic agents to penetrate the blood-brain barrier and arrive at their target destination.

Agents can be assayed by histopathological examination of the brains from such transgenic animals. For example, quantitative, microscopic analysis of amyloid plaque formation can be used to determine the effect of the agent. Agents which reduce the size or frequency of amyloid plaques are preferred. In addition, agents can be assayed by measuring brain levels of $A\beta_{1-40}$, $A\beta_{1-42}$, or $A\beta_{1-43}$ by radioimmunoassay or ELISA. Agents that reduce $A\beta_{1-40}$, $A\beta_{1-42}$, or $A\beta_{1-43}$ levels are preferred. Agents also can be assayed for their effect on the cognitive behavior of such animals using known methods. For example, the memory capability of mice can be determined using the water maize test. Agents which enhance the memory capability are preferred.

Agents that effectively reduce or inhibit Aß peptide production or amyloid plaque formation or increase memory in any of the methods described above can be used to treat or prevent AD. Persons identified as probable AD patients by known medical methods can be administered such agents. Also, people diagnosed as having a high probability of developing AD can be administered such agents. Patients are assessed for improvement in cognitive abilities. Upon autopsy, brain tissue is assessed for amyloid plaques and Aß

levels. Agents are administered by known methods such as those described above for the animal model.

Agents that effectively reduce or inhibit Aß peptide production or amyloid plaque formation or increase memory can also be used to enhance memory function of people, especially the elderly. People can be administered such agents and assayed for improved memory capability. Agents can be administered by known methods such as those described above for the in vivo assay.

The following examples are intended to illustrate but not limit the present invention.

EXAMPLE I

Isolation of Chromaffin Vesicles

Chromaffin vesicles were isolated from fresh bovine adrenal medulla by discontinuous sucrose gradient centrifugation (Krieger *et al., Biochemistry*, 31, 4223-4231, (1992); Yasothornsrikul *et al., J. Neurochem.* 70, 153-163, (1998)). Briefly, fresh bovine adrenal glands were dissected to obtain the medulla region. These medulla from 40 glands were homogenized in 200-250 ml ice-cold 0.32 M sucrose, and the homogenate was centrifuged at 1,500 rpm in a GSA rotor (Sorvall centrifuge) for 20 minutes at 4° C.

The resultant supernatant was collected and centrifuged at 8,800 rpm in a GSA rotor (Sorvall centrifuge) for 20 minutes at 4° C to obtain a pellet of chromaffin vesicles. The pellet of chromaffin vesicles was washed three times in 0.32 M sucrose. Each wash consisted of

resuspending the pellet of chromaffin vesicles with an equal volume (same volume as original homogenate) of 0.32 M sucrose and centrifugation at 8,800 rpm in a GSA rotor to collect the vesicles as the pellet.

After washing, the chromaffin vesicles were resuspended in 120 ml of 0.32 M sucrose and subjected to discontinuous sucrose gradient centrifugation. For that centrifugation, 10 ml of the washed chromaffin vesicle suspension was layered on top of 25 ml of 1.6 M sucrose in each of 12 centrifuge tubes. The 12 tubes of sucrose gradient were centrifuged in a SW28 rotor at 25,000 rpm for 120 minutes at 4° C. The pellets of isolated chromaffin vesicles from 12 tubes were resuspended in 12 ml of 0.015 M KCl with a glass-glass homogenizer, and stored at -70° C, prior to use. A chromaffin vesicle lysate was prepared by freeze-thawing the isolated chromaffin vesicles in the 15 mM KCl.

EXAMPLE II

Assay for Chromaffin Vesicles

The chromaffin vesicles in the Example I preparation were assayed for the chromaffin vesicle markers (Met)enkephalin, catecholamines, the lysosomal marker acid phosphatase and total protein. Fractions containing the highest amount of chromaffin vesicle markers were identified as chromaffin vesicles. The homogeneity of the chromaffin vesicles was approximately 99% as assayed by the proteolytic activity of the chromaffin vesicle markers (Met)enkephalin and catecholamines and the absence of the lysosomal marker acid phosphatase. Electron microscopy showed that uniform, homogeneous, and intact chromaffin vesicles were isolated. The chromaffin vesicles were purified approximately 8-fold from the cell homogenate based on the measurement of the picograms of (Met)enkephalin per microgram of protein in the samples.

EXAMPLE III

ß-secretase Endoprotease Activity

The APP substrate, Z*Val-Lys-Met-MCA, was used to identify a ß-secretase based on endoprotease activity. That substrate was commercially obtained and had a purity of 99% or better as determined by the manufacturers (PENINSULA LABORATORIES, Belmont, CA and PHOENIX LABORATORIES, Mountain View, CA).

The ß-secretase endoprotease activity was identified by incubating the chromaffin vesicle lysate (2-10 µl of 10-20 mg protein/ml) with the Z*Val-Lys-Met-MCA

substrate (100 µM final concentration) and detecting AMC fluorescence. The chromaffin vesicle lysate was prepared as described in Example I. The endoprotease activity was determined as a function of pH by varying the pH of the incubation solution between 3.0 to 8.0 in 0.5 pH increments. Citric acid, sodium phosphate, and Tris-HCl buffers (100 mM final concentration) were used to adjust the pH of the incubation solutions between 3.0 to 5.5, 6.0 to 7.5, and 8.0, respectively. Duplicate samples at each pH increment (100 µl each) were distributed among 22 wells in a covered microtiter well plate and incubated at 37° C for 8 hours in a water bath.

As discussed above, endoprotease cleavage between the Met-MCA bond in the Z*Val-Lys-Met-MCA substrate produces fluorescent AMC, but endoprotease cleavage between the Lys-Met or Val-Lys bonds in that substrate produces non-fluorescent Lys-Met-MCA and Met-MCA peptides. To insure that the latter two endoprotease cleavages were detected, aminopeptidase M (20 µg/ml final concentration, BOEHRINGER MANNHEIM) was added to each incubation solutions to produce fluorescent AMC from the Lys-Met-MCA and Met-MCA peptides. Prior to adding the aminopeptidase M, each incubation solution was adjusted to a pH 8.3 using Tris-HCl because aminopeptidase M functions at a basic pH. A second incubation at 37° C for 1 hour in the water bath was conducted to complete the aminopeptidase M reaction.

Upon termination of that second incubation, AMC fluorescence was assayed using a fluorometer (IDEXX fluorometer, FCA Fluorescence Concentration Analyzer, cat. no. 10-105-2, BAXTER HEALTH CARE CORP., Mundelein, IL) at

excitation and emission wavelengths of 365 and 450 nm, respectively. Standard AMC concentrations were also measured to quantitate relative fluorescence with the molar amount (pmol) of AMC generated by the secretase. The resulting AMC fluorescence reflects the endoprotease activity in cleaving either the Met-MCA, Lys-Met. and Val-Lys bonds in the Z*Val-Lys-Met-MCA substrate.

The AMC fluorescence was plotted as a function of pH and is shown in Figure 3. Analysis of that plot shows a principal β-secretase endoprotease activity having a pH optimum of about 4.5-5.0. In addition, the plot shows two lesser β-secretase endoprotease activities having pH optimums of about pH 3.5 and 6.0-6.5.

EXAMPLE IV

ß-secretase Aminopeptidase Activity

The APP substrates, Met-MCA, and Lys-MCA, were used to identify a ß-secretase based on aminopeptidase activity. Those substrates were commercially obtained and had a purity of 99% or greater as determined by the manufacturers (PENINSULA LABORATORIES, Belmont, CA and PHOENIX LABORATORIES, Mountain View, CA).

The ß-secretase Met aminopeptidase activity was identified by incubating the chromaffin vesicle lysate (5 µl of 10-15 mg/ml) with the Met-MCA substrate (100 µM final concentration) and detecting the resulting AMC fluorescence. The chromaffin vesicle lysate was prepared as described in Example I. The aminopeptidase activity was determined as function of pH by varying the pH of the incubation solution

between 3.0 to 8.0 in 0.5 pH increments. Citric acid, sodium phosphate, and Tris-HCl buffers (100 mM final concentration) were used to adjust the pH of the incubation solutions between 3.0 to 5.5, 6.0 to 7.5, and 8.0, respectively. Duplicate samples at each pH increment (100 µl each) were distributed among 22 wells in a covered microtiter well plate and incubated at 37° C for 4 hours in a humidified incubator.

Similarly, the ß-secretase Lys aminopeptidase activity was identified by incubating the chromaffin vesicle lysate (5 µl of 10-15 mg/ml) with the Lys-MCA substrate (100 µM final concentration) and detecting the resulting AMC fluorescence. The incubation was identical to that described for the Met aminopeptidase assay except that the incubation time was 2 hours long.

Upon termination of the incubations, AMC fluorescence was assayed as described above. The resulting AMC fluorescence indicating ß-secretase Met and Lys aminopeptidase activities was plotted as a function of pH and is shown in Figures 4 and 5, respectively.

Analysis of Figure 4 shows a β-secretase Met aminopeptidase activity having a pH optimum of about 5.5-6.5. Similarly, analysis of Figure 5 shows a β-secretase Lys aminopeptidase activity having a pH optimum of about 6.0-7.0.

EXAMPLE V

Identification of Aß peptides

The chromaffin vesicle lysate was analyzed for the proteolytic activity of Aß peptides using commercially available polyclonal and monoclonal antibodies against the $A\beta_{1-40}$ and $A\beta_{1-42}$ (PENINSULA LABORATORIES, Belmont, CA and QCB, Hopinton, MA, respectively) in known radioimmunoassay (RIA) and ELISA methods. The chromaffin vesicles contained $A\beta_{1-40}$ at 0.051 pg/ug protein as determined by RIA and a detectable amount of $A\beta_{1-42}$ as determined by ELISA.

EXAMPLE VI

APP Protein Distribution in Chromaffin Cells

The distribution of APP protein in chromaffin cells was determined using a monoclonal antibody directed against the amino terminal region of the APP protein (Anti-Alzheimer precursor protein A4, clone #22C11, BOEHRINGER MANNHEIM, Indianapolis, IN) in established immunofluorescent cytological methods. Fluorescent light microscopic analysis of chromaffin cells stained by this method showed that the APP protein was localized in the chromaffin vesicles and not in the cell nucleus.

EXAMPLE VII

Aß-peptide Secretion by Chromaffin Cells

Primary chromaffin cell cultures containing approximately 2 million cells in each culture were produced using established methods (Hook *et al., ibid.*; and Tezapsidis *et al., ibid.*). Exocytosis of the contents of

the vesicles in such cells was induced by exposing the cells to KCl (50 mM) or nicotine (10 μM) for 15 minutes. The media was removed from the cells and the $A\beta_{1-40}$ peptide in the media was determined using the RIA assay described in Example V. The KCl and nicotine exposure caused an approximately 350-fold and 550-fold increase in the concentration of $A\beta_{1-40}$ peptide in the media, respectively, relative to that of a control media from a culture identically processed but which did not receive KCL or nicotine. The results show that chromaffin cells exocytosis results in the secretion of Aß peptide.

EXAMPLE VIII

Effect of Reducing Agents on β-secretase Endoprotease Activity in Chromaffin Vesicles

The effect of the reducing agent dithiothreitol (DTT) on β-secretase endoprotease activity was determined using the assay described in Example III. Briefly, the lysed vesicles were incubated with the substrate Z*Val-Lys-Met-MCA in the presence or absence of 1 mM DTT and the resulting fluorescence plotted as a function of pH. Both with and without DTT, β-secretase endoprotease activity was detected and in both cases that activity had pH optimum of about 4.0 to 6.0, which is consistent with the intravesicular pH of chromaffin vesicles. But the DTT resulted in a significant increase in the β-secretase endoprotease activity, approximately 5-fold (see Figure 6). These results show that DTT, although not essential, significantly increases β-secretase endoprotease activity.

EXAMPLE IX

Effect of Aminopeptidase M on β-secretase Endoprotease Activity in Chromaffin Vesicles

The effect of the aminopeptidase M and the basic pH buffer used in the β-secretase endoprotease activity assay was determined. The assay was conducted as described in Example VIII with DTT. Three assays were conducted, one with aminopeptidase M in its basic pH buffer, another with the basic pH buffer but not aminopeptidase M, and a third without either the buffer or the aminopeptidase M. Briefly, the chromaffin vesicle lysate and the substrate Z*Val-Lys-Met-MCA were incubated for 30 minutes at a specified pH and the resulting fluorescence measured. The aminopeptidase M in the basic pH buffer or that buffer alone (final concentration of 75 mM Tris-HCl pH 8.2) was added to the assay and incubated an additional 60 minutes at 37°C. The resulting fluorescence was plotted as a function of pH, which showed that β-secretase endoprotease activity occurred in the 3 assays (see Figure 7). The assay conducted with aminopeptidase M and its basic pH buffer and that of the control assay having just the basic pH buffer produced approximately the same amount of fluorescence. This result is consistent with that obtained in Example IV, which showed that chromaffin vesicles contain an endogenous β-secretase methionine and lysine aminopeptidase.

EXAMPLE X

β-secretase Endoprotease Activity Obtained During Isolation of Chromaffin Vesicles

The β-secretase endoprotease activity of fractions obtained during the isolation procedure described in Example I was determined at the pH optimum of 5.5, with and without DTT using the assay described in Example VII. The ratio of those activities (with/without DTT) was calculated and the ratios obtained for the fraction shown in Table I.

TABLE I

FRACTION	RATIO
Adrenal Medulla Homgenate	4.7
Pellet from 1,500 rpm Centrifugation (nuclear fraction)	11.6
Pellet from 1st 8,800 rpm Centrifugation (crude vesicle fraction)	3.2
Pellet from 2nd 8,800 rpm Centrifugation (washed vesicle fraction)	6.3
Pellet from 25,000 rpm Discontinuous Gradient Centrifugation (vesicle fraction)	11.0

The results show that β-secretase endoprotease activity is enriched in the nuclear fraction and the vesicle fraction. But, as described in Example VI, only the chromaffin vesicles contain the APP protein, and thus only in that fraction does the protease having β-secretase endoprotease activity also have access to the APP protein substrate.

EXAMPLE XI

Protease Inhibitors of β-secretase Endoprotease Activity in Chromaffin Vesicle Lysate

The effect of various protease inhibitors on β-secretase endoprotease activity in the lysate was determined at the pH optimum 5.5 in the assay described in Example IX containing aminopeptidase M. Protease inhibitors specific for various protease classes were used. The protease inhibitor was added to each assay at the start of the reaction at the appropriate concentration. The extent of inhibition was expressed as a percentage of the activity without the inhibitor (control). Triplicate assays varied by less than 10%. The results are shown in Table II.

TABLE II

PROTEASE CLASS	INHIBITOR (Concentration)	% CONTROL
Control	None	100
Cysteine	E64c (10 μM)	0
Cysteine	pHMB (1 mM)	35
Serine	PMSF (100 μM)	58
Serine	Chymostatin (10 μM)	11
Aspartyl	Pepstatin A (10 μM)	78
Metallo	EDTA (1 mM)	100
Metallo	EGTA (1 mM)	99
Nonspecific	Leupeptin (100 μM)	0

The results show that the β-secretase endoprotease activity in the chromaffin vesicle lysate was completely inhibited by the cysteine protease class inhibitor E64c, and the nonspecific protease inhibitor leupeptin. The serine protease class inhibitor chymostatin and the cysteine protease inhibitor pHMB greatly inhibited activity. The apartyl protease class inhibitor pepstatin A slightly inhibited the activity and the metallo protease class inhibitors did not inhibit activity.

EXAMPLE XII

Isolation of β-Secretases from Chromaffin Vesicles

The chromaffin vesicle lysate was separated into 2 β-secretase endoprotease activity peaks (referred to as "Peak I" and "Peak II"). Peak I had about 3 times the total activity of Peak II and a different β-secretase endoprotease activity than did Peak II. The Peak I activity was very sensitive to the presence of aminopeptidase M in the assay whereas the Peak II activity was relatively insensitive to aminopeptidase M.

The Peak I center and range of activities had molecular weights of about 185 kDa, and about 180 to 200 kDa, respectively. Peak I was found to be a protease complex having a broad band of activity as determined by a native PAGE activity assay and 3 distinct activities corresponding to molecular weights of about 88, 81, and 61 kDa, in a non-reducing SDS-PAGE activity assay. Peak I was found to contain 3 proteins having molecular weights of about 88, 81, and 36 kDa, and 4 proteins having molecular

weights of about 66, 60, 33, and 29 kDa, in a non-reducing and a reducing SDS-PAGE stained for proteins, respectively.

Peak II had a center and range of activities having molecular weights of about 65 kDa, and about 50 to 90 kDa, respectively. Peak II contained 2 proteins having different net electronegative charges and β-secretase endoprotease activity (referred to as "Peak II-A" and "Peak II-B").

ISOLATION OF PEAKS I AND II AND CHARACTERIZATION OF THE β-SECRETASE ENDOPROTEASE ACTIVITES IN THOSE PEAKS

The procedure used to isolate Peaks I and II is diagramed in Figure 8. The β-secretase endoprotease activity with and without aminopeptidase M was determined after each isolation step using the assay described in Example IX. Isolation steps that enriched that activity were selected. The total and specific activities after each isolation step are summarized in Example XIII. The β-secretase aminopeptidase activity was determined by the assay described in Example IV.

Preliminary experiments indicated that the β-secretase is present in chromaffin vesicles at a relatively low concentration. Thus, a very large number of bovine adrenal glands, approximately 2400, was used so that a sufficient amount the β-secretase could be obtained for analysis. Using the methods described in Example I, numerous chromaffin vesicle lysate preparations were made over a period of approximately 6 months and pooled.

A soluble extract and membrane pellet from the pooled lysate was made by ultracentrifugation at approximately 100,000 x g. The bulk of the activity was in the soluble extract and was aminopeptidase insensitive (see Krieger, T.K. and Hook, V.Y.H. *J. Biol. Chem.* 266, 8376-8383, (1991). As such, it was concluded that the β-secretase endoprotease activity was not bound to the chromaffin vesicle membranes.

The soluble extract was separated by concanavalin A-Sepharose resin chromatography (referred to as "Con A") into bound and unbound fractions. The Con-A bound fraction was subsequently eluted using alpha-methylmannoside (referred to as the "eluted Con-A bound fraction") and contained the bulk of the β-secretase endoprotease activity, but no β-secretase aminopeptidase activity. The unbound fraction (referred to as the "Con-A unbound fraction"), in contrast, contained β-secretase methionine and lysine aminopeptidase activity, but little β-secretase endoprotease activity. The Con-A step thus separated the endogenous β-secretase endoprotease and aminopeptidase activities (see Krieger, T.K. and Hook, V.Y.H., *ibid.*).

The contents of the eluted Con-A bound fraction were fractioned according to molecular size using a Sephacryl S200 column (Krieger, T.K. and Hook, V.Y.H. *ibid.*). That resulted in the Peak I and Peak II β-secretase endoprotease activities. The Peak I center and range of activities corresponded to proteins having molecular weights of approximately 185 kDa, and 180 to 200 kDa, respectively. The Peak II center and range of activities corresponded to proteins having molecular weights

of approximately 65, and 50 to 90 kDa, respectively (see Figure 9).

Peak I had more than 3 times the total activity of Peak II, but the Peak I activity without aminopeptidase M was only about 5% of that produced with the aminopeptidase. Thus, Peak I was aminopeptidase sensitive. Since Peak I alone did not produce much fluorescence, the majority of the Peak I activity does not cleave the Met-MCA bond in the Z*Val-Lys-Met-MCA substrate because cleavage of that bond must occur to produce fluorescent free MCA. But since the addition of aminopeptidase M produced a significant amount of fluorescence, the majority of the Peak I activity must endoproteolytically cleave that substrate because that cleavage must occur, for reasons discussed above, in order for the aminopeptidase M to cleave the Met-MCA bond and the Lys-Met bond and produce fluorescent free MCA. The Peak I activity thus must cleave the Lys-Met or the Val-Lys bond because those are the only other peptide bonds in the substrate that can be cleaved. Moreover, the fact that aminopeptidase M must be added to Peak I to detect activity confirms that the Con-A isolation step removed most of the endogenous aminopeptidases from the eluted Con-A bound fraction.

As discussed above, the Met-MCA bond in the Z*Val-Lys-Met-MCA substrate is a mimic of the β-secretase scissile bond Met-Asp in the APP protein. As such, failure of the Peak I β-secretase endoprotease to cleave the Met-MCA bond means that it also does not cleave the β-secretase scissile bond. Rather, as discussed below, the majority of the Peak I β-secretase endoprotease activity

preferentially cleaves the Lys-Met in the β-secretase recognition site. Thus, for the Peak I β-secretase endoprotease to produce the amino terminal end of the Aβ peptide from an APP protein, several cleavages must occur. For example, the Peak I β-secretase endoprotease can cleave the Lys-Met bond adjacent to the β-secretase scissile bond and, second, an endogenous β-secretase aminopeptidase can cleave off the amino terminal Met in the β-secretase scissile bond Met-Asp to produce the amino terminal end of the Aβ peptide. Alternatively, the Peak I β-secretase endoprotease can cleave the Val-Lys bond and an endogenous β-secretase aminopeptidase(s) subsequently cleave off the Lys and Met amino acids and produce the amino terminal end of the Aβ peptide.

In contrast, Peak II was relatively aminopeptidase insensitive as its activity without aminopeptidase M was about 84% of that with the aminopeptidase. Thus, the majority of the Peak II activity cleaves the Met-MCA bond in the substrate Z*Val-Lys-Met-MCA directly because Peak II alone produces fluorescent free MCA. As the Met-MCA bond is a mimic of the β-secretase scissile bond, the majority of Peak II β-secretase endoprotease activity also cleaves the β-secretase scissile bond which can directly produce the amino terminal end of the Aβ peptide.

But the modest increase in the fluorescence produced by Peak II with aminopeptidase M indicates that some of the Peak II activity also cleaves the Lys-Met or the Val-Lys bond in the Z*Val-Lys-Met-MCA substrate for reasons described above regarding Peak I. Similarly, some of the Peak II activity also can produce the amino terminal end of

the Aβ peptide by a combination of endoprotease and aminopeptidase cleavages as discussed above regarding Peak I.

These results demonstrate that multiple β-secretases are involved in producing an Aβ peptide from an APP protein.

ISOLATION OF β-SECRETASES FROM PEAK I

The procedure used to isolate the β-secretases from Peak I is diagramed in Figure 10. The Sephacryl S200 column fractions containing the Peak I β-secretase endoprotease activity were pooled (referred to as the "Peak I Sephacryl S200 fraction") and chromatographed on a chromatofocusing Polybuffer Exchange 94 column (PHARMACIA, Piscataway, NJ, referred to here as "CF"). The CF fractions containing the β-secretase endoprotease activity were pooled and concentrated with buffer exchange to 100 mM citric acid-NaOH, pH 4.5, using an AMICON ultrafiltration apparatus equipped with a YM 10 membrane. (referred to as the "Peak I CF fraction" or "CF fraction," see Krieger, T.K. and Hook, V.Y.H., *ibid.*).

The Peak I CF fraction, in turn, was purified using cation Mono S exchange chromatography by FPLC (referred to as "Mono S"). The CF fraction was loaded onto a Mono S ion exchange FPLC column (1 ml HiTrap column SP, PHARMACIA, Piscataway, NJ) that was equilibrated with 100 mM citric acid-NaOH, pH 4.5 (referred to as "buffer A"). The column was eluted with a NaCl gradient generated with a buffer consisting of 100 mM citric acid-NaOH, pH 4.5, 2.0 M

NaCl (referred to as "buffer B"), with the gradient consisting of 0% buffer B at 1-15 min., 0-25% buffer B at 15-45 min., 25-100% buffer B at 45-50 min., 100% buffer B at 50-55 min., 100-0% buffer B at 55-60 min., and 0% buffer B at 60-75 min., with a flow rate of 1ml/min. Fractions containing β-secretase endoprotease activity were pooled and concentrated by AMICON ultrafiltration with buffer exchange to 100 mM citric acid-NaOH, pH 4.5 (referred to as the "Peak I Mono S fraction" or "Mono S fraction").

The Mono S fraction was further analyzed by various polyacrylamide gel electrophoresis (PAGE) methods. Referring in Figure 10, one such method was a "native PAGE in gel activity assay," which determined the β-secretase endoprotease activity of the Mono S fraction in the PAGE gel. In this assay, the proteins are first separated by electrophoresis and then allowed to proteolytically react with a suitable substrate in the gel. Proteins having proteolytic activity are identified by the formation of a cleavage product in the gel. A suitable substrate and cleavage product for detecting a secretase in this assay is an APP substrate and an APP derived product. The APP derived product can be detected by various methods such as those described above, but fluorescent detection methods are preferred. The PAGE in gel activity assay can also be used to detect proteases other than secretases using suitable substrates. The in gel activity assay may also use other suitable gels, such as, for example, agarose. In contrast to the PAGE in gel protein staining assays described below, the PAGE in gel activity assay determines only those proteins having protease activity rather than all proteins.

In a native PAGE in gel activity assay, the sample is in a solution which preserves protein complexes composed of proteins associated together by non-covalent and covalent bonds in their "native" state. Thus, a native PAGE in gel activity assay can determine the proteolytic activity of a protein complex. If a protein complex has such activity, that complex is referred to as a "protease complex." A protease complex is two or more proteins associated together by a non-covalent bond, such as, for example, an ionic bond, or a non-peptide covalent bond, such as, for example, a disulfide bond, and at least one of the proteins has protease activity. A β-secretase protease complex is a protease complex that cleaves an APP substrate.

Referring to Figure 10, another PAGE method that the Mono S fraction was subjected is the "non-reducing SDS-PAGE in gel activity assay." Like the native PAGE in gel activity assay, the non-reducing SDS-PAGE in gel activity assay also determined the β-secretase endoprotease activity of the Mono S fraction in the PAGE gel. But this assay differs in that it contains the detergent SDS, hence the term "SDS-PAGE." SDS separates proteins associated together by a non-covalent bond. A "non-reducing in gel assay" means that the assay does not contain a reducing agent, such as, for example, β-mercaptoethanol. Such reducing agents sever covalent disulfide bonds between and within proteins. Thus, in the non-reducing SDS-PAGE in gel activity assay, proteins associated by a non-covalent bond are separated from each other but those proteins that are linked by a disulfide bond are not.

The substrate used in all in gel activity assays was the peptide Z*Phe-Arg-MCA (PENINSULA LABORATORIES, San Carlos, CA). The Phe-Arg-MCA sequence of that sequence mimics the Val-Lys-Met sequence in the β-secretase recognition site because both contain a hydrophobic amino acid adjacent to a positively charged amino acid and the MCA group, as discussed above, mimics a P1' amino acid. As such, cleavage of the Arg-MCA bond in the Z*Phe-Arg-MCA substrate is equivalent to cleaving the Lys-Met bond in the β-secretase recognition site or in the Z*Val-Lys-Met-MCA substrate. That later substrate was not used for the in gel assay because, as discussed above, an aminopeptidase is required to detect cleavage of that substrate by Peak I.

Native PAGE in gel activity assays were conducted as follows. The Z*Phe-Arg-MCA substrate was embedded into the gel by copolymerization of Z*Phe-Arg-MCA (250 µM) with resolving gel (8 7 x 0.1 cm, NOVEX gel cassette, San Diego, CA) components consisting of 12% polyacrylamide with 0.16% bis-acrylamide and 0.375 Tris-HCl, pH 8.8. The stacking gel was 6% polyacrylamide, 0.16% bis-acrylamide, and 0.125 M Tris-HCl, pH 6.8, prepared according to Laemmli (Laemmli, U.K. *Nature* 227:259, 680-685 (1970)). The Mono S fraction (2-4 µl) was prepared in native sample buffer containing 50 mM Tris-HCl, pH 8.3, and 2% glycerol, and electrophoresed in the gel at 4°C in a running buffer consisting of 25 mM Tris-HCl, 192 mM glycine, pH 8.3 for 2.5 hours at a constant current of 25 mAmp. The gel was then washed in cold 2.5% Triton X-100 solution for 10 minutes, and with cold sterile water for 10 minutes. ß-secretase endoprotease cleavage of the substrate Z*Phe-Arg-MCA embedded in the gel was conducted by incubating the gel at 37°C for 2 hours in 100

mM citric acid-NaOH, pH 5.0, 1 mM EDTA, 1 mM DTT, and 10 mM CHAPS. AMC fluorescence in the gel was visualized under a UV transilluminator. The fluorescent image was photographed with Kodak DC120 digital camera, and analyzed with the EDAS120 image software system, which allows quantitative image analysis.

The native PAGE in gel activity assay of the Peak I Mono S fraction resulted in a wide broad band of faint fluorescence. That result is characteristic of a protease complex and shows that the activity in Peak I is due to a protease complex. Moreover, the result shows that the protease complex cleaves the Arg-MCA bond because that cleavage must occur for fluorescence to be detected and fluorescence was detected without an aminopeptidase being present. Since the Arg-MCA bond in the Z*Phe-Arg-MCA substrate is equivalent to the Lys-Met bond in the β-secretase recognition site, the protease complex also cleaves the Lys-Met bond in that substrate.

The non-reducing SDS-PAGE in gel activity assay was conducted as described for the native PAGE in gel activity assay, except that the stacking and resolving gels contained 0.1% SDS, the sample buffer contained 1.5% SDS, and the electrophoresis was conducted for 1.5 hours. The non-reducing SDS-PAGE in gel activity assay showed 3 distinct, precise and intense fluorescent bands corresponding to proteins having molecular weights of approximately 88, 81, and 66 kDa. The 3 proteins cleaved the Arg-MCA bond in the Z*Phe-Arg-MCA substrate because fluorescence was produced without aminopeptidase. Moreover,

those proteins also cleave the Lys-Met bond in the ß-secretase recognition site for the reasons discussed above.

The Peak I Mono S fraction was also subjected to "preparative native PAGE." This electrophoresis method was used to further isolate the β-secretases. Native conditions using the MiniPrep Cell system (BIORAD, Richmond, CA). Tube gels (7 mm internal diameter) were prepared with the resolving gel (10 cm) consisting of 6% polyacrylamide (with 0.16% bis-acrylamide and 0.375 M Tris-HCl, pH 8.8) and a stacking gel (1 cm) of 4% polacrylamide (with 0.11% bis-acrylamide and 0.125 M Tris-HCl, pH 6.8), prepared according to the manufacturer's protocol. The Mono S fraction (200 to 300 µl) in native sample buffer containing 25 mM Tris-HCl, 192 mM glycine, pH 8.3, and 10% glycerol was subjected to electrophoresis in the native tube gel at a constant power of 1 watt at 4° C for 48 hours in running buffer consisting of 25 mM Tris-HCl, 192 mM glycine, and pH 8.3. During electrophoresis, fractions (0.6 ml/fraction) were eluted in running buffer at a flow rate of 0.02 ml/minute; stability of eluted β-secretase endoprotease activity was improved with adjustment of fractions to pH 6.0 using an equal volume of 0.1 M citric acid-NaOH, pH 4.5. Fractions were immediately assayed for Z*Val-Lys-Met-MCA cleavage in the presence of aminopeptidase M, or for Z-Phe-Arg-MCA without aminopeptidase M as described (Azaryan, A.V. and Hook, V.Y.H., *FEBS Lett.* 341, 197-202 (1994)). After preparative native gel electrophoresis, one peak of β-secretase endoprotease activity was observed for cleavage of the substrate Z*Val-Lys-Met-MCA.

The preparative native PAGE sample containing the activity was further analyzed by various PAGE methods, including the non-reducing SDS-PAGE in gel activity assay described above. That assay resulted in the same 3 activity bands having molecular weights of about 88, 81, and 61 kDa obtained from the Mono S fraction run in that assay.

The preparative native PAGE sample was also analyzed in a non-reducing SDS-PAGE in gel protein staining assay which detects the proteins present in the gel. In contrast to the in gel activity assay, the protein staining assay detects all proteins present in a sufficient amount to be detected without regard to protease activity. The non-reducing SDS-PAGE in gel protein staining assay was conducted in a similar manner as the activity assay, but was silver stained to identify the proteins and resulted in 3 definite and precise bands corresponding to proteins having molecular weights of about 88, 81, and 36 kDa.

The results obtained from the non-reducing SDS-PAGE in gel protein staining and activity assays were compared. The 88 and 81 kDa proteins observed by silver staining correlated with the two ß-secretase endoproteolytic activities at those weights in the activity assay. But no protein was detected in the protein staining assay corresponding to the 61 kDa activity band. This result implied that the amount of protein at that position may have been insufficient to be detect by silver staining. If that is the case, the 61 kDa protein had a very high specific activity because intense activity was observed at that position. No activity was detected in the activity assay at the position corresponding to the 36 kDa protein, indicating

that the 36 kDa protein does not have β-secretase endoproteolytic activity.

The preparative native PAGE sample was further analyzed in a reducing SDS-PAGE in gel protein staining assay. Like the staining assay described above, this assay also detected the proteins present in the gel without regard to proteolytic activity. But since this assay was conducted in the presence of a reducing agent, ß-mercaptoethanol, disulfide bonds were severed. The assay was run as described above for the protein staining assay except that the gel and sample buffer contained ß-mercaptoethanol. Four proteins having molecular weights of approximately 66, 60, 33, and 29 kDa were detected.

The reducing SDS-PAGE in gel protein staining assay resulted in more and on average proteins of lower molecular weight than did the corresponding non-reducing assay. That difference indicates that the preparative native PAGE sample contained proteins having disulfide bonds which were severed by the reducing agent to produce a larger number of proteins with lower molecular weights. In particular, the 88 and 81 kDa proteins had such bonds severed because only lighter proteins were observed under reducing conditions. The 33 and 36 kDa proteins obtained under reducing and non-reducing conditions may be the same protein because their weights are similar.

The results obtained from the reducing SDS-PAGE in gel protein staining and the non-reducing SDS-PAGE in gel activity assays were compared. The 88 and 81 kDa proteins having activities contained one or more disulfide bonds that

were severed under the reducing conditions. The 60 kDa and 61 kDa proteins in silver staining and activity assays were about the same weight and may be the same protein.

ISOLATION OF β-SECRETASES FROM PEAK II

The procedure used to isolate Peak II-A and Peak II-B from Peak II is diagramed in Figure 11. The Sephacryl S200 fractions containing Peak II were pooled and further purified using Mono Q ion exchange FPLC chromatography (referred to as "Mono Q FPLC"). The fraction that did not bind to that column contained Peak II β-secretase endoprotease activity (referred to as the "unbound Peak II" or "Peak II-A"). The fraction that bound to the column was eluted using a NaCl gradient from zero to 0.5 M NaCl, and also contained Peak II β-secretase endoprotease activity (referred to as "bound Peak II" or the "Peak II-B"). Peak II-B was further purified by a second Mono Q column, with elution of the β-secretase activity by a pH gradient of pH 7.0 to pH 4.0 generated by polybuffer 74 (PHARMACIA, Piscataway, NJ), performed as described previously (Krieger, T.K. and Hook, V.Y.H., *ibid.*). Since Mono Q FPLC is an anion exchange chromatography, the unbound Peak II is a protein that is less electronegative than the Peak II-B protein.

EXAMPLE XIII

β-secretase Endoprotease Activities Obtained During Isolation of β-secretases

The total (relative fluorescence units/0.5 hr) and specific (relative fluorescence units/mg protein) of the

β-secretase endoprotease activity without and with aminopeptidase M (-APM, +APM, respectively) was determined for fractions obtained in the isolation procedure described in Example XII. All assays were conducted as described in Example IX. The activities obtained are summarized in Table III.

TABLE III

ISOLATION STEP	TOTAL ACTIVITY		SPECIFIC ACTIVITY	
	-APM	+APM	-APM	+APM
Lysate	11	12	1.8	1.9
Soluble extract	12	12	2.6	2.5
Membrane	0.4	0.6	1.7	2.3
Con-A bound[a]	19	75	367	1.5×10^3
Con-A unbound[b]	8	9	2	2
		Peak I		
Sephacryl S200	13	275	2.0×10^3	4.2×10^4
CF fraction	38	496	3.0×10^3	3.8×10^4
Mono S fraction	16	300	5.0×10^5	9.3×10^6
Prep. SDS-PAGE	ND[c]	30	1.0×10^7	2.0×10^7
		Peak II		
Sephacryl S200	63	75	6.0×10^4	7.2×10^4
Mono Q FPLC Peak II-A	15	16	5.5×10^5	6.0×10^5
Mono Q FPLC Peak II-B	6	6	3.1×10^4	4.4×10^4

[a] No β-secretase aminopeptidase activity detected

[b] β-secretase aminopeptidase activity detected

[c] Not done

The total activity of the lysate and the soluble extract without aminopeptidase M was about 92% and 100% of that with the aminopeptidase, respectively, and thus were aminopeptidase insensitive. The soluble extract contained about 100% of the total activity in the lysate, but the membrane pellet contained only about 4% of that activity, indicating that the β-secretase endoprotease activity is not bound to the chromaffin vesicle membranes.

The eluted Con-A bound fraction assayed without and with aminopeptidase M had about 158% and 625% of the total activity in the lysate, respectively. The increase in the total activity indicated that an inhibitor or competitive substrate, such as APP protein, may be removed at this step. The eluted Con-A bound fraction had a total activity that was somewhat aminopeptidase sensitive as the activity without aminopeptidase M was approximately 25% of that with the aminopeptidase.

The Con-A unbound fraction contained the *endogenous* β-secretase aminopeptidase activity which was not present in the eluted Con-A bound fraction. As such, Peak I and Peak II subsequently purified from the eluted Con-A bound fraction did not contain significant endogenous aminopeptidase activity.

Peak I from the Sephacryl S200 isolation step was highly aminopeptidase sensitive, having a total activity of only about 4.7% without aminopeptidase M as and with the aminopeptidase. Moreover, Peak I assayed with the aminopeptidase had about 367% and 2292% of the total activity in the eluted Con-A bound fraction and lysate,

respectively, again indicating possible removal of an inhibitor or competitive substrate.

Continuing with the isolation of Peak I, the CF fraction also was aminopeptidase sensitive as the total activity without aminopeptidase M was about 7.6% of that with the aminopeptidase. Again the total activity was increased, this time by about 180% and 4,133% of that from the Sephacryl S200 fraction and the lysate, respectively, as measured with aminopeptidase M and again raising the possibility that an inhibitor or competitive substrate was removed.

The Mono S fraction of Peak I remained very aminopeptidase sensitive, having a total activity without aminopeptidase M of about 5.3% of that with the aminopeptidase. But the total activity of the Mono S fraction was about 60% and 2,500% of that in the CF fraction and lysate, respectively. This indicates that the Mono S isolation step may lose some activity but that the activity remains well above that in the lysate.

The preparative SDS-PAGE isolation of Peak I resulted in 10% and 250% of the activity in the Mono S fraction and lysate, respectively. Moreover, the activity after this step, unlike the previous isolation steps, became quite unstable indicating that the preparative SDS-PAGE isolation step may remove an activator or stabilizing agent.

Returning to the isolation of Peak II by Sephacryl S200, the Peak II had about 27% of the activity of Peak I. In other words, Peak I had about 3 times more β-secretase

endoprotease activity than did Peak II. But Peak II was relatively aminopeptidase insensitive as the total activity without aminopeptidase M was about 84% of that with the aminopeptidase. Peak II total activity assayed with aminopeptidase M was the same as that in the eluted Con-A bound fraction indicating that this isolation step does not remove an inhibitor, an APP substrate, an activator, or a stabilizing agent.

After Mono Q FPLC isolation, Peak II-A and Peak II-B were found to be aminopeptidase insensitive. The combined total activity of Peak II-A and Peak II-B was about 32% of the total activity in the Sephacryl S200 fraction with aminopeptidase M. Peak II-A and Peak II-B had a total activity of about 133% and 66% of that in the lysate, respectively.

The specific activity showed that a very high degree of isolation was obtained. Specifically, the preparative SDS-PAGE electrophoresis isolation step of Peak I resulted in about a 0.5×10^6 and 1.0×10^6 purification from the chromaffin vesicle lysate as analyzed without and with aminopeptidase, respectively. The Mono Q FPLC isolation of Peak II-A resulted in a 2.3×10^5 and 3×10^5 purification from the chromaffin vesicle lysate as analyzed without and with aminopeptidase, respectively. The Mono Q FPLC isolation step of the Peak II-B resulted in a 1.5×10^4 and $2,2 \times 10^4$ purification from the chromaffin vesicle lysate as analyzed without and with aminopeptidase, respectively.

EXAMPLE XIV

Protease Inhibitors of β-secretase Endoprotease Activity in Peaks I and II

The effect of various protease inhibitors on β-secretase endoprotease activity in Peaks I and II was determined by the method described in Example XI. The results were expressed as a percent inhibition of the control (no inhibitor) is summarized in Table IV.

TABLE IV

PROTEASE CLASS	INHIBITOR (Concentration)	Peak I (%)	Peak II (%)
Control	None	100	100
Cysteine	E64c (10 μM)	0	0
Cysteine	pHMB (1 mM)	67	68
Serine	PMSF (100 μM)	90	112
Serine	Chymostatin (10 μM)	0	35
Aspartyl	Pepstatin A (100 μM)	85	132
Metallo	EDTA (1 mM)	99	138
Metallo	EGTA (1 mM)	108	142
Metallo	1,10 Phenanthroline (500 μM)	31	72
Nonspecific	Leupeptin (100 μM)	0	0

Peak I and Peak II activities were maximally inhibited by the nonspecific protease class inhibitor leupeptin, the cysteine class inhibitor E64c, and the serine protease class inhibitor chymostatin. The other cysteine class inhibitor, pHMB, slightly inhibited both activities.

The other serine protease class inhibitor, PMSF, did not significantly inhibit either activity. The metallo protease class inhibitor 1,10 phenanthroline significantly inhibited Peak I, but only slightly inhibited Peak II. The other metallo protease class inhibitors and the aspartyl protease class inhibitor pepstatin A did not significantly inhibit either activity.

Peak I and Peak II activities were identically inhibited by the cysteine protease class and nonspecific protease class inhibitors. The serine, aspartyl and metallo protease classes inhibitors tended to inhibit Peak I activity more than Peak II.

The inhibition of Peak I and Peak II activities was compared with that obtained for the chromaffin vesicle lysate (Example XI). All 3 activities were completely inhibited by the cysteine protease class inhibitor E64c and the nonspecific protease class inhibitor leupeptin. The serine protease class inhibitor chymostatin and the cysteine protease class inhibitor pHMB inhibited all activities, although the Peak I and Peak II activity was inhibited less than that of the lysate. The serine protease class inhibitor PMSF significantly inhibited the lysate activity but only slightly inhibited the Peak I and Peak II activities. The aspartic protease class inhibitor pepstatin A slightly inhibited the lysate and Peak I activities but increased the activity of Peak II. Except for the 1,10 phenanthroline, none of the metallo class protease class inhibitors inhibited any activity and, in some cases, increased the activity.

EXAMPLE XV

Confirmation of Cleavage Specificities of the Peak I, Peak II-A, and Peak II-B β-Secretase Endoprotease Activities

As discussed above, the substrates Z*Val-Lys-Met-MCA and Z*Phe-Arg-MCA mimic the β-secretase recognition site in the APP protein. The fluorescent MCA that resulted from the cleavage of those substrates established the cleavage specificities of the Peak I, Peak II-A, and Peak II-B β-secretases. In particular, those results showed that the majority of the endoprotease activity in Peak I cleaved the Lys-Met bond amino terminally adjacent to the β-secretase scissile bond in the β-secretase recognition site of the APP protein. Those results also showed that the majority of the endoprotease activity in Peak II-A and Peak II-B cleaved the β-secretase scissile bond in the β-secretase recognition site of the APP protein.

To confirm the Peak I cleavage specificity, electrospray mass spectrometry (EMS) was also used to analyze the APP derived products resulting from the cleavage of the Z*Val-Lys-Met-MCA substrate by the Peak I activity. The cleavage assay was conduced by the method described in Example XII without aminopeptidase M. The APP derived products were then analyzed by a commerical EMS facility (SCRIPPS RESEARCH INSTITUTE, La Jolla, CA). The EMS analysis confirmed that the Peak I activity cleaved the Lys-Met bond in the Z*Val-Lys-Met-MCA substrate.

To confirm the cleavage specificities of the Peak I, Peak II-A, Peak II-B activities, another APP substrate was reacted with each of those activities and the APP

derived products analyzed by EMS. The APP substrate Ser-Glu-Val-Lys-Met-Asp-Ala-Glu-Phe (SEQ ID NO.:5) contains the 5 amino terminal and 4 carboxyl terminal amino acids to the β-secretase scissile bond in the APP protein. The substrate was commercially produced and purified to greater 95% purity by standard reverse phase high pressure liquid chromatography methods. The cleavage assay of Example XII was used without the aminopeptidase M and without the Z*Val-Lys-Met-MCA substrate, but with the Ser-Glu-Val-Lys-Met-Asp-Ala-Glu-Phe (SEQ ID NO.:5) substrate (14 µg/assay). The APP derived products were then subjected to a C8 reverse phase high pressure liquid chromatography, eluted with an acetonitrile gradient in 0.1 % TFA (trifluoroacetic acid), the peptides identified by absorbance spectroscopy at 210-215 nm and collected (see Krieger T.K. and Hook V.Y.H., ibid. and Krieger et al., *J. Neurochem.* 59, 26-31 (1992)). The EMS data of the eluted APP derived products confirmed that the majority of Peak I activity cleaved the Lys-Met bond and that the majority of the Peaks II-A and II-B activities cleaved the Met-Asp bond.

EXAMPLE XVI

The Endoproteolytic Activity of Peak I is due to Cathepsin L

This example demonstrates that the ß-secretase activity of Peak I is due to cathepsin L.

Peak I was purified as described in Example XII. The protease responsible for ß-secretase endoprotease activity of Peak I, was affinity labeled with DCG-04, a biotinylated analogue of the cysteine protease inhibitor

E64c, a compound that inhibits the ß-secretase activity of Peak I.

An aliquot of Peak I was incubated at room temperature with 125I-DCG-04 for 30 minutes, and the affinity labeled ß-secretase was then subjected to one-dimensional SDS-PAGE followed by electrophoretic transfer of proteins to nitrocellulose membranes, and 125I-DCG-04 labeled proteins were detected with streptavidin-HRP, as described previously (Greenbaum et al. Chem. Biol. 7:569-81, 2000, Greenbaum et al., Chemistry and Biology 10, 1085-1094, 2002; Greenbaum et al., Mol. Cell. Proteomics, 1:60-68, 2002).

Affinity labeling of Peak I with 125I-DCG-04 resulted in labeling of protein bands having an apparent molecular weight of 31 kDa and 27 kDa by SDS-PAGE. The 31 kDa band resembles the molecular weight of the cysteine protease cathepsin B (Barrett et al., "Handbook of Proteolytic Enzymes," Pub. Academic Press, SanDiego, pp 609-617, 1998; and Greenbaum et al., Mol. Cell. Proteomics, 1:60-68, 2002). The selective cathepsin B inhibitor, CA-074, was used to determine whether the 27 kDa or 31 kDa bands were responsible for the ß-secretase activity of Peak I (Yamamoto et al., J. Mol. Biol. 227:942-944, 1992; Gour-Salin et al., J. Med. Chem. 36:720-725, 1993; Bogyo et al., Chem Biol. 1:27-38, 2000). The ß-secretase activity of Peak I was completed inhibited by E64c (at 1 µM), but was not affected by CA-074 (1 µM concentration). Moreover, specific 125I-DCG-04 labeling of Peak I in the presence of CA-074 (1 µM) resulted in labeling of only the 27 kDa band, and not the 31 kDa band. These results indicate that the 27

kDa cysteine protease band represents the ß-secretase activity of Peak I.

The 27 kDa cysteine protease band was determined to be bovine cathepsin L by tandem mass spectroscopy achieved by LC-MS as previously described. These findings demonstrate that ß-secretase activity of Peak I is due to cathepsin L. That 27 kDa band was also found to have proenkephalin cleaving activity (Yasothornsrikul et al., Biochemistry, 38:7421-7430, 1999, Yasothornsrikul et al., submitted 2003). The amino acid sequences of cathepsin L from many different species, as well as the nucleic acids encoding those sequences, are known and are highly conserved (see, for example, Kirschke, H. "Cathepsin B, Cathepsin H and Cathepsin L," in Methods of Enzymology, 1981:80 Pt.C pp. 535-561 and SwissProt data base).

EXAMPLE XVII

The Endoproteolytic Activities of Peak II-A and Peak II-B are Due to Cathepsin B

This example demonstates that the ß-secretase activity of Peak I is due to cathepsin L.

Peak II-A and Peak II-B were purified as described in Examples XII and XIII and affinity labeled with 125I-DCG-04 and processed as described in Example XV. The labeling of both Peaks resulted in a single 31 kDa cysteine protease band. The protease activities in both of the 31 kDa band were completely inhibited by the selective cathepsin B inhibitor, CA-074 (1 micromole). Moreover,

125I-DCG-04 labeling of the 31 kDa bands from both Peaks was completely inhibited by CA-074.

The DCG-04 labeled 31 kDa protein band of Peaks II-A and II-B were detected by silver staining. Purified Peak II-A contained only the 31 kDa band. However, Peak II-B contained the 31 kDa band, as well as 55 and 66 kDa bands that were not labeled with DCG-04. To identify the 31 kDa protein band, it was excised from the SDS-PAGE gel and subjected to peptide microsequencing by tandem mass spectrometry of tryptic peptides. Results indicated detection of tryptic peptides with primary sequences that correspond to bovine cathepin B. These findings demonstrate that the ß-secretase activities of Peaks II-A and II-B consist of cathepsin B. The amino acid sequence of cathepsin B from numerous species, including human, are known, as are the nucleic acid encoding those sequences and are highly conserved (see, for example, Kirschke, H. "Cathepsin B, Cathepsin H and Cathepsin L," in Methods of Enzymology, 1981:80 Pt.C pp. 535-561, and SwissProt data base).

EXAMPLE XVIII

Immunoelectron Microscopic Localization of Cathepsin L and Cathepsin B Within Secretory Vesicles

This example demonstrates the presence of cathepsin L and cathepsin B within secretory vesicles.

The presence of cathepsin L and cathepsin B within secretory vesicles was confirmed by immuno electron microscopy. In brief, chromaffin vesicles were isolated

from fresh bovine adrenal medulla by differential sucrose density centrifigation, as previously described (Yasothornsrikul et al., J. Neurochem. 70:153-163, 1998). Vesicles were fixed in 0.2% glutaraldehyde, 2% paraformaldehyde in 0.1 M sodium cacodylate buffer, pH 7.2 for 30 minutes, washed three times in cacodylate buffer, and osmicated in 2% osmium tetroxide in 0.1 M cacodylate buffer for 30 min at room temperature; samples were dehydrated through graded ethanols, infiltrated through propylene oxide and embedded in Epon 812. Preservation and ultrastructural integrity of the granules was examined in a Tecnai-12 transmission electron microscope (FEI, Phillips, Eindhoven, Netherlands).

The cathepsins were detected by immunoelectron microscopy was performed, as described previously (Hook et al., Endocrinol. 140:3744-3754, 1999). Ultrathin sections were collected on nickel grids, partially deosmicated through 1% periodic acid/9% sodium periodate, washed in 1X Tris buffered saline (TBS), and incubated in 3% normal goat serum in 1X TBS. Primary antisera to cathepsin L or cathepsin B (Athens, Georgia) were diluted to 1:100 in 1% normal rabbit serum in TBS and was applied to the sections for two hours at room temperature. Sections were washed in TBS and incubated with the secondary goat anti-rabbit IgG conjugated to 15 nm colloidal gold (Aurion, Wageningen, Netherlands). Sections were washed with TBS and double distilled water, and examined by TEM. Electron micrographs were taken at several magnifications using a CCD camera and Digital Micrograph Software (Gatan Inc., Pleasanton, CA). Visual analysis of the micrographs was used to determine that cathepsin L and cathepsin B are present in the

secretory vesicles. The same vesicles containing the cathepsin also contain APP and Aß peptides. Cathepsin L and catepsin B thus are located in the subcellular site containing their substrate and product where they function in vivo as ß-secretases.

EXAMPLE XIX

Disease Drug Discovery Assays

This example describes drug disovery asssays targeting Cathepsin L or Cathepsin B.

Recently, the cyseine proteases of Peak I and Peak II were shown to contain the vast majority of in vivo ß-secretase activity, accounting for approximately 95% of the Aß peptide production (Hook et al., J. Neurochem. 81:237-256, 2002). In particular, the cysteine proteases in those Peaks were shown to be particularly effective at cleaving the ß-secretase site in wild-type APP, the APP present in over 95% of AD patients. As such, inhibition of that ß-secretase activity is an effective means by which to reduce treat AD.

The instant discovery that cathepsin L and cathepsin B are the ß-secretases of Peak I and Peak II, respectively, now allows for the use of those cathepsins as screens for selecting AD drugs. In particular, such screens can be used to select for compounds that are themselves effective for treating AD or for compounds that will lead to development of such compounds.

Many methods are known in the art for using a known protease as a target to select compounds that inhibit it and any of those methods can be adopted to screen for compounds that effect cathepsin L and cathepsin B. Such means include, for example, those based on in vitro chemical reactions between a compound and a cathepsin L or cathepsin B molecule. In such a system, a compound's effect on the enzymatic activity of cathepsin L or cathepsin B on an APP substrate can be assayed and inhibitors selected that reduce the activity. The reduced ß-secretase activity can be assayed by any means known or those described herein For example, the reduced ß-secretase activity caused by such a compound can be assayed by detecting a reduced production of one or more AB peptides or a reduced production of the 12 -14 kDa COOH-terminal APP fragment that contains the ß-secretase domain. Such production can be detected by any means known in the art for doing so and those described herein. Such inhibitors can act by any means that effects the activity of cathepsin L or cathepsin B or both. For example, an inhibitor can bind to the active site on a cathepsin L or cathepsin B molecule and thereby reduce the activity of the cathepsin. An inhibitor can also act by binding to a domain distal to the active site on a cathepsin L or cathepsin B molecule and thereby reduce the activity. The compound can also inhibit by binding to the APP substrate and thereby block its cleavage by the cathepsin.

In vitro chemical reactions also include those between a compound and one or more other molecules known to effect the production of cathepsin L or B. For example, cells are known to produce enzymatically inactive procathepsin L and procathepsin B froms which are

proteolytically cleaved into enzymatically active forms. The amino acid and nucleic acid sequences of procathepsin L and procathepsin B are known as are many enzymes capable of producing active cathepsin L and cathepsin B. Thus, compounds can be selected for that inhibit the proteolytic conversion of procathepsin L and procathepsin B to cathepsin L and cathepsin B, respectively, and thereby reduce cathepsin L and cathepsin B activity.

In vitro chemical reactions also include those between a compound and one or more other molecules known to effect the activity of cathepsin L or B. Many molecules are known in the art to effect cathepsin L or cathepsin B activity. For example, the molecule P41, a splice variant of the major histocampatibility complex (MHC) class II associated invariant chain contains a segment that acts as a chaparone for cathepsin L by both inhibiting the activity of cathepsin L and stabilizing its structure. Thus, in vitro chemical reactions can select for compounds that alter the effect of P41 on the cathepsin L activity. Other molecules are also known in the art to effect the activity of cathepsin L and cathepsin B and any of these molecules can also be used to select for AD compounds.

Assays also include cell assays that select for compounds that inhibit ß-secretase activity of cathepsin L or cathepsin B. For example, as described herein, chromaffin or neuronal cells can be used for this purpose. The reduction in activity in such cells can be determined by a variety of means such as, for example, by detecting the reduction in the production of one or more AB peptides or a reduced production of the 12 -14 kDa COOH-terminal APP

fragment that contains the ß-secretase domain. In particular, AB peptide production can be detected in cells induced to undergo exocytosis as described herein. A compound can reduce the activity of cathepsin L or cathepsin B activity in such cell assays by a variety of means. For example, a compound can reduce the ß-secretase activity by effecting the proteolytic cleavage capability of cathepsin L or cathepsin B for APP substrates. A compound can also inhibit that activity by reducing the production of cathepsin L or cathepsin B. The production can be effected at any point in the cell production of cathepsin L or cathepsin B, including at the transcription, translation, and post-translational processing levels.

Assays also include animal assays for selecting compounds that reduce the ß-secretase activity of cathepsin L or cathepsin B. The reduction in that activity can be assayed by a variety of means such as, for example, by detecting a reduction in the production of one or more AB peptides by means known in the art or described herein. In a particular embodiment, the production of AB peptide in the central nervous system can be assayed. Normal or known transgenic AD model animals can be used for this purpose. Assays also include patient assays for monitoring the effectiveness of such inhibitors for reducing AB peptide production in patients. In particular, such methods as those described in U. S. Patent No. 5,338,686, can be adapted to measure production of one or more AB peptides by a patient receiving such an inhibitor.

Assays further include in silico assays that select for compounds based on the known structure of cathepsin L or cathepsin B. Such structural analysis can be

based on a wide range of data sources ranging, for example, from the known amino acid sequence structure to the known three-dimensional atomic resolution crystal structure of cathepsin L or cathepsin B. Especially useful crystal structures for this purpose are the active sites of the cathepsins in which APP substrates are cleaved (see, for example, Fujishima, A. et al., Febs. Lett. 407:47-50, 1997; Guncar G, et al. EMBO J. 1999 Feb 15;18(4):793-803; Yamamoto A, et al., J Biochem (Tokyo), 2000 Apr;127(4):635-43; Yamamoto A, et al. J Biochem (Tokyo). 2000 Apr;127(4):635-43; Yamamoto A, et al., Biochim Biophys Acta. 2002 Jun 3;1597(2):244-51). Moreover, the assays also include those based on rational drug design using known structures of compounds that effect cathepsin L or cathepsin B activity or structure. Such in silico assays are known in the art and can be readily applied to determine effective inhibitors.

EXAMPLE XX

Known Cathepsin L or Cathepsin B Inhibitors as Alzheimer's Disease Drugs

Numerous inhibitors of cathepsin L or cathepsin B are known in the art. Such compounds found by searching the literature using known methods for doing so including, for example, by finding such compounds via computer searches of data bases, such as patent and scientific publication data basis. Inhibitors known to be effective in vivo for altering cathepsin L or cathepsin B activity can be as AD drugs or further developed into even more effective drugs using known medicinal chemistry methods. Inhibitors not

known to be effective in vivo can, nonetheless, be used to develop AD drugs using known medicinal chemical methods.

Compounds known that inhibit cysteine proteases generally can be used for such purposes. Such compounds are described, for example, in U.S. Patent Nos. 5,925,633, 5,925,772, 5,776,718 and 6,468,977. Such compounds include, for example, E64c and derivatives thereof, such as, for example, E64d. E64c has been administered to animals and shown to effectively block cathepsin activity in brain.

Many compounds are known to selectively inhibit cathepsin L that can be used as AD drugs or AD drug development. For example, a series of inhibitors referred to as cathepsin L inhibitor Katunuma (CLIK) have been developed which were found to selectively inhibit cathepsin L (see, for example, Katunuma et al., FEBS Lett. 458:6-10, 1999, Katunuma et al., Arch. Biochem & Biophy. 397:305-311, 2002a, and Katunuma et al., Advan. Enzyme Regul. 42:159-172, 2002b). These compounds are based on a common structure of N-(trans-carbamoyloxyrane-2-carbonyl)-L-phenylalanine-dimethylamide. The prototype compound of this series of inhibitors is CLIK-148 (N-(L-3-trans-[2-(pyridin-2-yl)ethylcalbamoyl-oxirane-2-calbonyl]-1-phenylalanine dimethylamide. CLIK-148 inhibited purified rat cathepsin L activity in the submicromolar levels and completely inhibited activity at 1 uM (Katunuma et al. 1999). In contrast, it had no effect on purified rat cathepsin B activity at 10 uM and only had minimal activities on cathepsins K, S and C at micromolar levels. Intraperitoneal injection of CLIK-148 to mice dose dependently inhibited cathepsin L activity in liver while

having no effect on cathepsin B activity (Katunuma et al. , 1999, ibid). Both cancer metastasis and osteoporosis are believed to be due to actions of cathepsin L in degrading collagen. Intravenous or p.o. administration of CLIK-148 blocked bone metastasis of the cancer cells Colon-26 and the human melanoma cells A375 in mice and blocked cancer induced osteoporosis (Katunuma et al. 2002a, ibid) consistent with the inhibitory actions of CLIK-148 on cathepsin L activity.

Additional cathespin L inhibitors were developed by Rydzewski et al. Bioorganic & Medicinal Chem. 10:3277-3284, 2002 using a 1-cyano-D-proline scaffold. In particular, the compound 1-cyano-(D)-prolylleucine benzyl ester was developed that selectively inhibits cathepsin L and that compound completely inhibited cathepsin L activity in DLD-1 cells while having minimal activity on cathespin B.

Many other compounds have been found to inhibit cathepsin L. Such compounds include those described by Chowdhurry, SF., et al., J, Med. Chem. 45(24):5321-5329, 2002; Yamamoto, Y. et al,, Curr . Protein Pept. Sci. 3(2):231-238, 2002; Asanuma, K., et al., Kidney Int. 62(3):822-831, 2002; Saegusa, K., et al., J. Clin. Invest. 110(3):361-369, 2002; Rigden., DJ., Protein Sci. 11(8):1971-1977, 2002; Schaschke., N. et al., Biol. Chem. 383:849-852, 2002; Sever, N.et al., Bio. Chem. 383(5):839-842, 2002; Wang., D., et al., Biochemistry 41(28):8849-8859, 2002; Katunuma, N., et al. Arch. Biochem. Biophys. 397(2):305-311, 2002; Irving, JA, et al. J. Biol. Chem. 277(15):13192-13201, 2002; Kurata, M., et al., J.

Biochem (Tokyo) 130(6):857-863, 2001; Kusunoki, T., et al. J. Otolaryngol. 30(3):157:161, 2001.

Many compounds are also known to selectively inhibit cathepsin B and can be used for AD drugs or drug development. For example, compounds have been developed that are selective cathespin B inhibitors based on a series of dipeptidyl nitriles starting with the compound Cbz-Phe-NH-CH2CN (see, for example, Greenspan et al., J. Med. Chem 44:4524-4534, 2002). In particular, the compound N-[2-[(3-Carboxyphenyl)methoxyl-1-(S)-cyanoethyl]-3-methyl-N-(2,4-difluorobenzoyl)-L-phenylalaninamide has been shown to inhibit recombinant human cathepsin B activity but is approximately 100-fold less potent in blocking cathepsin L or cathepsin S activities.

The compound CA-074 has also been shown to be a selective inhibitor of cathepsin B (see, for example Jane, DT., et al., Biochem Cell Biol. 80(4):457-465, 2002; and Montaser, M., et al., Bio Chem. 383(7-8):1305-1308, 2002).

Many other compounds are also known to selectively inhibit cathpsin B. Such compounds include those described by Niestroj, AJ., et al. Biol. Chem. 383(7-8):1205-1214, 2002; Cathers, BE., et al. Bioorg. Chem. 30(4):264, 2002; Guo,. R., et al. Biochem Biophys. Res. Commun. 297(1):38-45, 2002; Wieczerzak, E, et al. J. Med. Chem. 45(19):4202-4211, 2002; Van Ackjer, GJ., et al., Am. J. Physiol. Gastrointest. Liver Physiol. 283(3): G794-800, 2002; Schaschke, N., et al. 2002, ibid; Sever, N., et al., 2002, ibid; Wang et al., 2002 ibid; Yamamoto, A. 2002 ibid; Irving, JA., 2002 ibid; and U.S. Patent No. 5,550,138.

Without exception, each of the references cited above is expressly incorporated herein in its entirety. Although the invention has been described with reference to the examples provided above, it should be understood that various modifications can be made without departing from the spirit of the invention. Accordingly, the invention is limited only by the claims.
